VOL. CXXII, No. 1 NEW YORK, WEDNESDAY, JULY 1, 1925 WHOLE NO. 2308

The New Surgery*

HOWARD A. KELLY, M.D.
Baltimore, Md.

I speak from a considerable experience with several important but still novel additions to our surgical technic, namely, bipolar electrocoagulation and monopolar desiccation of William A. Clark and electric molecular disintegration by the cutting needle of George A. Wyeth. Clark calls the electric principles involved in his procedure by the established name, diathermy, while Wyeth seeks to emphasize the differences between these currents in their already well known medical and their more recent surgical uses by the term endothermy.

ACUSECTOR

Let us consider first the needle functioning as a knife and actually separating tissues as neatly and as readily as a scalpel. To avoid the to me objectionable name, radioknife, I call this instrument in my own clinic, an acusector (*acu,* with a needle; *seco,* I cut), or briefly, "sector." It consists of a light sterilizable fibre handle armed with a needle longer, shorter, or bent, according to the work to be done, in circuit with a sterilizable cord. This new fashioned scalpel is held delicately poised in the fingers like a pen and used as a sort of wand to divide the tissues which actually part before they are touched.

There must be no pressure whatever and no delay at any point as the tissues yield, a circumstance which at first presents a slight difficulty to one only accustomed to manipulating a scalpel. By slight regulations of the current, the operation proceeds more or less rapidly. For delicate dissections of nerves and vessels, as for example in high breast axillary work, the current is cut down to a minute gentle stream. In mass dissection, as in cutting through pedicles or removing larger amounts of disease, a heavier current is registered. In dividing the skin, it is desirable to use a current strength between the two to secure efficiency and yet not to penetrate more than a tenth of a millimeter laterally. Divided lymphatics are thus sealed and there is a notable diminution in capillary oozing. The dissection is far more beautiful and cleaner, more rapid and more satisfactory than any knife work, especially in separating intraabdominal adhesions. A delicate and difficult dissection advances by slow impulses or gentle strokes in regions where there is some uncertainty as to what lies immediately beyond. There is much less mopping and delay over capillary oozing, while larger vessels are often seen and clamped before they are divided and later coagulated and dropped or ligated if necessary. There is throughout less handling of the wound in this forceps and needle procedure, the operator in a sense having a curious gratifying consciousness of holding himself aloof from it. While by no means altogether rejecting the scalpel, I give the sector the leading place and decided preference in my daily work, relegating the scalpel to a subordinate position. It remains to be seen in the division of the skin whether the advantage lies with a skilful use of the sector or with the scalpel in the matter of subsequent primary union. The sector also has a remarkable field in conjunction with coagulation, under which heading I shall speak of it again.

The handle can be made, say, twenty-two cm. long for deep abdominal work. Twitching of any of the larger muscles touched can be lessened by cutting down the current or by grasping the muscle firmly with forceps before dividing. There is one real danger due to the fact that the division of the tissues ahead of the needle point proceeds in a manner so remarkable and so unexpected that one might easily sever peritoneum and contiguous bowel with one slight stroke. As the depth of the opening depends not on the force exerted by the hand wielding the sector but upon the current, there is no such dropping away of the underlying bowel as occurs with a cautious use of a scalpel. The dissection does not, therefore, proceed as we are accustomed to see it by easy stages and layer by layer, but simply dead ahead through every contiguous structure. It is most important also to remember this danger of any contact whatever while dissecting near large vessels such as the axillary, especially when the pectoralis is jerking. The interposition of a wooden spatula here will obviate trouble.

I think I have said enough to show that we have here a remarkably startling invention and innovation, for probably the last thing any one of us ever anticipated was that the time honored scalpel, badge of our office as surgeons as it were, would ever find a successful rival. How unsafe it is to prophesy!

*Read before the American Academy of Physiotherapy at the meeting held in Atlantic City, May 25 and 26, 1925.

Copyright, 1925, by A. R. Elliott Publishing Company.

DESICCATION

Desiccation is a process of Clark's by which the high tension of a monopolar spark played at the end of a needle into the more or less superficial tissues dehydrates and reduces them to a dry even powdery condition in which they can be wiped or gently scraped away. The underlying area is sterilized by this procedure and can be kept so by suitable dressings until a rapid, almost scarless healing, has taken place. Any pain from the use of the current is obviated by local injections of a weak solution of novocaine. There is a large field for desiccation in the removal of moles, fibrous growths, other skin blemishes, and superficial epitheliomata, as well as in hemorrhoids. Desiccation is also invaluable in rapidly wiping out flat or slightly elevated papillary growths disseminated over the peritoneum. An important use is over the base of an area which has been bared by the sector, to stop hemorrhage and seal lymphatics. In a large sacculated hernia of the linea alba, I recently destroyed the whole peritoneal lining with desiccation and then closed the abdominal wall and secured primary union. I propose to extend this principle to inguinal and femoral and other hernias, destroying the sac *in situ* and leaving it there!

COAGULATION

Coagulation calls for the bipolar current also delivered at a needle point, and breaks down the cellular structure of the tissues and condenses them into a necrotic mass (Asnis). An average action extends readily 0.5 cm out into the tissues in all directions. We here enter a vast beneficent new field. The impression as the needle is inserted and the current turned on by one who uses it for the first time is that of a minute or of a heavy explosion of lightning within the tissues. Let us examine this somewhat carefully, taking as an illustrative case an epithelioma say half an inch in diameter on the face. By whatever method we elect to attack such a lesion, we calculate to deal with the entire area of obvious disease plus that circumjacent area or zone of the surrounding tissues we judge likely to be involved in the invisible extensions which in time reproduce the disease. For example, no sane surgeon will remove merely the obviously involved area, as repeated experiences have long since shown that a rapid recurrence is invariable. So whether we use a caustic paste, following my old friend and teacher in dermatology, Herman Duhring, or a scalpel, or electrocoagulation, or radium, we calculate to destroy or affect a wide zone of the surrounding tissues, operating more or less superficially according to the extent of the lesion and the known tendencies of the disease. Our successes and our failures, aside from the question of metastases, are wholly determined by this zone factor, and the penumbra, the doubtful region.

In the old fashioned bloody surgical operations commonly in vogue, I now begin to think with some repulsion of the messiness of the procedure, the sponging, the tying, the needling, and the general manipulations of the wound which must contribute to many bad results.

I therefore welcome this new method of coagulation as a great addendum to our technic, not only enabling us to do some things better, but greatly enlarging our field of beneficent activity.

Following Wyeth in many cases I would proceed as follows: Outline my field by circumscribing the suspected area by a rampart of coagulation, shutting off all lymphatics and destroying the tissues on the outermost periphery, a procedure which I think deserves the special term of "circumvallation." Then with the Wyeth sector the whole area is cut into like cheese and as a plaque is lifted up and off. Then the base is dealt with by a thorough desiccation.

ADVANTAGES OF THE METHOD

These great advantages gradually dawn upon us as we gain experience with these new methods:

1. There is no squeezing or manipulating the tissues, and no needling or insertion of ligatures.
2. The field is kept sterile or made sterile and can so continue through the healing process.
3. Healing generally takes place rapidly and without pain.
4. Granulations later may necessitate grafting.
5. If any part has been insufficiently treated, the first effort can be followed up at any subsequent time with ease and simplicity in this differing *toto celo* from our ordinary surgery.
6. I believe that in some cases it will actually be well to divide the operation up into a series in this way until all the disease is chased out of its terrain.

Bleeding vessels are caught with painstaking accuracy with fine pointed forceps (I prefer them slightly curved) and then sealed by touching the forceps with the current which is delivered with force at the point thus coagulating only a small area and occluding the vessel (Ward).

In some cases the whole concept of an operation differs from our present day bloody surgical methods. For example, in a disease of indeterminate extent about the face the surgeon commonly cuts rapidly around the area and then proceeds to remove all within the zone, while by our methods of sector and coagulation and desiccation we can proceed inward and onward, often removing tissue as we go and chasing the disease into the depths as far as it extends and where it is inaccessible to the scalpel. This is rendered possible by the constant control of the bleeding and by the comfort the operator finds in his work when he is not wasting time applying ligatures. Where larger vessels come into the field a preliminary ligation near the vessel trunk may be advisable.

Coagulation and the sector also render invaluable service where a failure with radium has left thickened devitalized tissues in contact with the disease.

I have used it with the best results in chronic cervicitis, also in destroying cervical cancer and cleaning out a deep pocket into which the radium was then inserted, securing a far better application.

Through an open air cystoscope made of hard rubber (not a necessity) I have coagulated, destroying completely, a large bladder tumor and have dealt easily with smaller disseminated growths. In vesicovaginal fistula the sector starts the operation delightfully by circumscribing the area over which the bladder is to be loosened from the vagina. This is often awkward with scalpel or scissors.

Eye surgeons are destined to find a large use for the desiccator in delicate work on mucosa and sclerotica, especially in dealing with early malignancy.

It is easy to see that these great new principles are destined to command an extensive readjustment of the surgical field, adding enormously to the satisfaction of the operator and the comfort of the patient; in a large percentage of our cases scalpel and ligature surgery, the old method, is destined soon to seem obsolete and crude when compared with the new which is neater, cleaner, and more effective.

Several other important advances I foresee at once. About a year ago I removed an epithelioma of the cutis of the penis two cm. in diameter with coagulation; I then cut down onto a large obviously cancerous gland in the left groin, punctured it with the needle, coagulated the whole interior, and sewed up the skin without removing it; the recovery was perfect and there has been no recurrence. This little step opens up a large vista in such fields as these:

Groups of cancerous glands in iliac fossa; glands on floor of pelvis in uterine cancer; glands deep down in fork of vessels in such cancer as ileocecal; glands in neck; glands in gastric cancer. It may even limit resection of stomach to pyloric region by destruction of the glands along the border in this way. I think also it is applicable to any single deep abdominal glands we occasionally meet which we would be glad to destroy.

In papilloma of peritoneum or disseminated malignancy, or in any localized malignant area which cannot well be removed on account of the condition of patient, or the site of the lesion, this maneuvre may be found to be effective.

A small malignant nodule on the intestinal wall I would destroy and then sew sound bowel over it.

SUMMARY

In conclusion, let me summarize: we have at our disposal a set of new agents destined to remodel our surgical technic over a large field.

1. The new electric methods are not simple substitutes or alternative methods of doing what we have done equally well by other procedures.

2. These methods are not to be learned completely in a week or a year. They call for careful attention to a new technic, for discriminating judgment in their application and for increasing boldness with a growing experience. The concept is a new one.

3. They will succeed often where surgery and radium have failed, although they do not exclude or wholly supplant either.

4. In operating by these new methods the motto might well be stated as "hands off," as there is so little fingering of the tissues.

5. Not least of the advantages of the new procedures are those of lessening hemorrhage, a more rapid disposal of diseased and infected tissues and a considerable shortening of the duration of the operation.

6. A larger percentage of the cases can be treated as ambulatory, after being treated under local or short gas anesthesias.

7. Pain owing to the destruction of the sensory nerves is lessened.

8. Healing is better.

If these allegations are true they fully justify the title "new surgery."

1406 Eutaw Place.

Electrocoagulation in Surgery*

WILLIAM D. McFEE, M.D.
Boston, Mass.

Electrosurgery now occupies a distinctive sphere in surgical work, inasmuch as it may be used with safety and brings satisfactory results in the treatment of many conditions heretofore dangerous and inaccessible by the employment of knife surgery. Very often the surgeon encounters pathological conditions which he hesitates or refuses to attack because of the liability of meeting with uncontrollable hemorrhage, either for the reason that the tissue itself is such that it will not retain ligatures or because sloughing subsequent to operation may extend to neighboring bloodvessels and troublesome secondary hemorrhage follow.

In the use of electrosurgery we have at our command an agent which is readily controlled and which, in the hands of one trained and experienced in its use, may be employed with entire safety. Electrosurgery comprises the use of electricity in its many forms for the destruction of tissue.

One effect of the contact of high frequency currents producing a certain degree of heat is the coagulation of bodily structure or tissue.

While interesting results from the use of other forms of electricity in destroying tissue have been noted, none of them has attracted so much general attention on the part of the medical profession as has the use of this modern high frequency electrical application in the treatment of many forms of skin lesions and growths of both malignant and non-malignant types.

The success achieved by surgical electrical procedures has also increased the interest in all forms of electrotherapeutics.

Surgical applications of electricity produce either a thermal or a chemical action on tissue, and their action is in no sense dependent on the temperament of the individual; this is in contradistinction to the medical use of electricity which is to a great extent influenced by individual reactions. Consequently in surgery we have a definite demonstration of what actually takes place, and this has been a leading factor in awakening the interest and attention of our profession to the possibilities of the use of electricity in its many forms for the treatment of various medical and surgical conditions.

The use of electrocoagulation to destroy growths by the heat action of the high frequency current is followed by very little sloughing of tissue, and

*Read before the American Academy of Physiotherapy at the meeting held in Atlantic City, May 25 and 26, 1925.

very little postoperative pain; it is attended with no blood loss, thus conserving the energy of the patient and giving to the operation the minimum of danger.

To practise surgery successfully with the high frequency current, one must first have a satisfactory equipment; there is a great deal of high frequency apparatus now in the market, good, bad and indifferent. In selecting the apparatus which he is to use one should make a thorough investigation and try to determine just what is best for the particular work which he intends to accomplish; too much reliance should not be placed on the statements of the manufacturer or the salesman whose chief object is to effect the sale of his goods.

For the purposes of electrosurgery an apparatus should be obtained which has a constant and consistent output of current, and which will produce the required quality of spark or contact heat effect. For all round purposes of electrosurgery one of the ordinary oil immersed transformers made by a reliable concern is to be preferred; of these there is the large type and the small, which is portable. Of the portable machines very few are reliable for heavy work, such as the treatment of large, thick growths.

The spark gap which regulates the quality and volume of the electrical discharge is a very important part of the apparatus; it has to be cleaned and adjusted from time to time, so that some attention should be paid to this in choosing an apparatus for our use.

Reference to the term electrocoagulation in this paper will mean the deep destruction or coagulation of tissue by the high frequency current in direct contact, by means of the active electrode connected with one terminal in conjunction with the indifferent electrode connected with the other terminal of the high frequency machine, and applied at any convenient part of the body situated opposite, or near, the part treated; this constitutes the bipolar high frequency application. This may be used for the removal of many forms of cancer which are external or accessible in cavities, also in treating deep-seated growths after they are exposed by means of the ordinary surgical procedure.

There is very little sloughing beyond the border of current contact, and scarcely any pain or other disagreeable reaction following the treatment; blood-vessels and lymph channels are immediately sealed so that there is no blood loss, and these possible entrances for the migration of diseased cells are thus effectively shut off and closed.

The best results in this work, particularly in those cases of inaccessible growths, will be obtained by the joint efforts of the surgeon skilled in the knowledge and use of knife surgery, and the surgeon having similar knowledge of and skilled in the surgical use and action of electricity. To know when to do and what to do under particular circumstances with either or both of these methods requires much painstaking study and observation and much practical experience. Many instances have been reported of absolute failures and many awkward situations have been encountered when surgeons, unaccustomed to and unacquainted with the action of electrical currents, have attempted to make use of them. It has been well said that "electricity is a good servant and a bad master."

Recently I was present when a sorry spectacle occurred in the amphitheatre of a large hospital in which a prominent surgeon, well skilled and proficient in his own line of work, undertook the destruction of a growth by electrocoagulation, using a volume and character of current which was in no way adapted to the condition he was treating, with the result that too much destruction took place; and the operator proceeded to condemn the apparatus used when, as a matter of fact, the real fault was his own lack of proper knowledge of the agent he was using.

Such unfortunate demonstrations bring discredit on this line of work which is as unwarranted as it is unnecessary, for the surgeon should either call to his assistance one who has special knowledge of the action and uses of electrical currents or should qualify himself in this field before attempting to enter it.

In the operation for the removal of cancer, the following technic has been successfully employed by the writer:

An active electrode, consisting of a surgical knife, fitted in an insulated handle, is used in contact with the tissue to be removed. A large indifferent metal electrode is applied to some opposing surface, the patient under general anesthesia. The current used is that delivered from a good high frequency apparatus of the D'Arsonval type which will deliver a high milliamperage and remain constant in action. The current is turned on by an assistant and gradually increased until coagulation appears, as shown by the cooking of the tissue. The knife, which is inserted just beyond and below the margin of the growth, is then gradually moved through the circumference with a rotary motion, the growth being lifted with the other hand by means of a suture imbedded in the structure or by forceps. As it becomes separated this is continued until the growth is entirely removed. If conditions and technic are right, no bleeding should result and a clean, seared surface is assured. Very little if any pain follows, and a superficial slough occurs.

The method of electrocoagulation is adapted to a great variety of lesions and growths in many parts of the body, and my interest has been particularly attracted to the good results obtained in the treatment of a number of cases similar to the following:

Case I.—J. S., aged eighty, was operated on by me for the removal of a papillary carcinoma, about the size and thickness of an English walnut, at the base of the tongue, according to the following technic: The patient was anesthetized with ether, the head being raised and the mouth propped open with a mouthgag placed in the opposite side of mouth; the tongue was held in position by a long suture passing through its centre; the cheek was divided by a lateral incision extending from the angle of the mouth to a point midway to the angle of the jaw, thus exposing the growth which was removed by cutting it away with a knife electrode according to the method of electrocoagulation previously described. There was no bleeding, as all vessels were immediately closed off by the heat

from the current as the operation proceeded. The surface left, after removal, was gone over by the desiccation spark and the line of demarcation was well beyond the diseased tissue. The absence of bleeding makes it much easier to visualize just what is taking place in the operative field, and we are thus able to perform our work with more definite accuracy. By this method we are also more sure of destroying malignant cells which may be at some distance beyond the growth, thus diminishing any tendency toward recurrence.

Case II.—R. W., aged fifty-five, was operated on by me two years ago for the removal of an extensive leucoplakia involving the cheek adjacent to the left lower jaw; this case had been previously treated by radium for one year with no result except that the disease was much aggravated, the patient suffering considerable pain after each application. The radium treatment in this case was given by a physician who was skilled in its use through many years' experience. The diseased tissue was removed by electrocoagulation; the indifferent metal electrode, size eight by ten inches, was placed under the shoulders and the surgical knife, in an insulated handle, was used as the active electrode; this was carried around the growth beyond its margin, the growth being gradually lifted from its bed as it was separated by the current contact. Sloughs covered all the coagulated area, which is usual, and these separated in about two weeks. During this time the patient was able to be about every day, had very little discomfort, required no narcotics, and had no blood loss during or after the operation. Up to the present time the area treated has held its full degree of improvement.

Although frequent reference has been made by many writers to the dangers of ether as an anesthetic where high frequency currents are used, I have as yet experienced no trouble in this respect although caution has been exercised, particularly in not allowing any spark to escape, by not breaking the contact of the electrode with the tissue until the current is shut off by the assistant.

In the use of electrocoagulation or surgical diathermy our aim is to produce under the active electrode an intense application of electrical heat so as to completely destroy the tissue operated on. In this operation the indifferent electrode is large, usually not less than eight by six inches, and placed on any portion of the body where good contact may be obtained. The active electrode which I prefer is one which resembles the ordinary surgical scalpel. The amount of current used will differ at all times, being subject to a difference in the resistance of the tissues themselves, and also varying in different types of apparatus used.

Malignant conditions involving the mucous membranes, as cancer of the tongue, leucoplakia, etc., usually respond very little if any to treatment by x rays or radium alone, but remarkable results are secured when electrocoagulation is used followed in some cases by ultraviolet radiation or x ray. In coagulating tissue which is close to bony structures care should be exercised not to coagulate deeply enough to destroy the periosteum, as it takes considerable time, even many months in some cases, for this to heal. The entire bone structure may be destroyed when necessary. Caution should also be exercised in all these treatments to see that the indifferent electrode closely approximates the skin surface; it should be held in place by a bandage preferably of elastic material, so that if the patient moves it is not so easily dislodged. Very severe burning may result from loose or improper electrical contact due to the arc formed in the air space between the electrode and skin; good electrical contact therefore must be maintained throughout the entire operation.

Electrocoagulation, if properly performed, should be followed by no surgical shock, no hemorrhage, and no loss of blood during or after the operation. In treating growths in the mouth, sometimes our coagulation will not go beyond the point of actual contact, and it is well to watch these cases during the sloughing process so as to guard against possible bleeding when the slough begins to separate; this, however, will very seldom occur. While the operation of electrocoagulation is going on, if any bleeding should occur, it may be immediately controlled by applying the active electrode to its source.

While the foot switch may be used by the operator to turn the current on and off, it has the disadvantage of dividing his attention between his hands and feet; also, when using the foot switch, the current strength cannot be regulated, so that for the ordinary purposes of any electrocoagulation operation the aid of a good assistant, stationed at the apparatus, who can quickly change the control switch of the transformer so that it will deliver a greater or less amount of current, changing at once when signalled by the operator, gives the most satisfactory results.

The operator may disregard any meter reading when using electrical currents to coagulate, as his best guide is his observation of the changes taking place, or in other words, the reaction in the destroyed tissue. The amount and character of current used, together with the time of its application, must depend largely on his knowledge gained from previous experience.

A high frequency apparatus having a set of radio tubes in circuit will produce a current giving a constant and steady intense heat effect which will quickly cut its way through the tissues, using an ordinary needle for the active electrode; but according to my understanding, this method when used alone is not dependable for producing the desired extent of coagulation without getting too much destructive action at the point of contact; in other words, unless the active needle electrode is kept moving the tissues will be charred and this may be followed by more extensive sloughing.

It is rather deplorable that such a term as radio-knife is used, since the action of the current referred to in this application is due to the radio tubes used in the circuit, producing what is called the undamped wave, thus maintaining a constant heat effect which is in no way dependent on the terminal applicator or electrode used. In all of our work we should make use only of language and expressions or terms which convey definite information or meaning.

The dissection of the growth by using the high

frequency current with the spark gap in circuit and the surgical knife for the active electrode will certainly produce some most interesting results.

I believe this work has a wonderful future field of usefulness, as it will no doubt be given increased attention by those in our profession who are qualified to develop its many important qualities.

27 White Street.

Digestive Symptoms Caused by Disease of the Abdominal Vessels

*With Special Reference to Arteriosclerosis**

I. W. HELD, M.D.
New York

The frequency of gastrointestinal symptoms resulting from general arteriosclerosis and those occurring in the course of localized cerebral or thoracic arteriosclerosis, is well known. Although marked arteriosclerosis of the abdominal vessels either as a part of general arteriosclerosis or localized to the abdominal vessels only is not infrequent, its clinical significance has not been sufficiently appreciated.

Physiologically, the distribution of blood throughout the body undergoes variations depending on the amount of blood the functioning organ needs. If the organ performs a maximum amount of work, the blood supplied to that particular organ is far greater than to the rest of the body. E. Weber showed that a muscle when performing its maximum amount of work might receive seven times the quantity of blood it contained during rest. It is also known that two thirds of the total quantity of blood may be held by the vessels of the skin. The vessels in the lower abdomen, known as the largest blood reservoir in the human body, may contain an unusual quantity of blood at the expense of other parts of the body.

The distribution of the blood in the body is automatically regulated by the splanchnic nerves. Stimulation of the splanchnic nerves increases the vascular tone, causing contraction of the small arteries and the arterioles. Paralysis of the splanchnic nerves causes marked dilatation of the bloodvessels. The vasomotor changes influencing the smallest vessels determine to a large extent the distribution of the blood supply to the organs proper. These vasomotor changes are brought about to a considerable degree by rhythmic contractions in the capillaries (Krogh, Hooker and Danzer, E. P. Boas, and others). The splanchnic bloodvessels in the lower abdomen play an important rôle in the distribution of blood to the abdominal organs.

The coordinate work of the nerves and the flow of the blood through the bloodvessels may be interfered with by innervation disturbances or by organic changes in the vessels. Where the proper blood supply to an organ is interfered with on account of innervation disturbances in the bloodvessels, the condition may be termed angioneurosis; interference with the proper functioning of the bloodvessels on account of organic changes may be termed angiosclerosis (Walko). It is apparent that at times, especially during middle life, it is quite impossible to differentiate clinically whether we are dealing with a purely functional disorder of the bloodvessels (angioneurosis) or an organic disorder (angiosclerosis). Huchard, in order to avoid confusion, designates even the functional disorders of the bloodvessels as presclerosis. The term presclerosis is not appropriate from the clinical point of view, because it expresses merely a speculative possibility. Pathologically, the term presclerosis is justifiable.

In order to understand the symptom complex caused by arterial disease, it is important to dwell somewhat in detail on the pathology of arteriosclerosis and to a certain degree on its pathogenesis.

The epoch making work of Jores on arteriosclerosis is today almost universally accepted with some modifications by the most recent workers, such as L. Aschoff, A. Aschoff and the former's pupils (Hueck and Faber), MacCallum of this country, and by Evans and Adami of England.

It is known that the changes in the different vessels in general arteriosclerosis are not uniform. In the intima of the aorta and the other large vessels of the elastic type, there exists during embryonic life an elastic muscular layer. In the course of life two more layers develop, the first being the result of the formation of a new elastic layer arranged in lamellæ and originating from the lamina elastica interna and known as the hyperplastic layer. On the inner aspect of this layer there is another layer from which it is separated with difficulty. This inner layer consists almost exclusively of connective tissue and contains elastic fibres not in the form of lamellæ. This layer of connective tissue may be diffuse or be present only in small areas; in the latter case it is designated as sclerotic plaques. According to Jores this connective tissue layer is preceded in its formation by fatty degeneration in the elastic, muscular and hyperplastic layers and is therefore of a reparative nature.

According to L. Aschoff the fatty changes do not affect the elastic tissue but the cement substance of the vessels and are not necessarily of a degenerative nature, but the result of infiltration of cholesterol carried to the vessels with the blood plasma. Degenerative changes need not precede the formation of connective tissue. Accordingly, the fatty changes, as evidenced by excess of lipoids, replace the elastic fibres without the formation of connective tissue, or connective tissue formation may be present without being preceded by fatty degeneration. During the ascent of life, and even before puberty, such fatty changes are encountered in the vessels of the elastic type which may retrogress. These changes depend entirely, according to Aschoff, on the excess of cholesterol in the blood and are therefore of a metabolic nature. Such changes were not encoun-

*Read before the Eastern Medical Society, November 14, 1924.

tered during the World War because of the scarcity of fat in the diet. It may be mentioned here that the marked increase of the cholesterol content of the blood causes deposition of the cholesterol in the wall of the bloodvessels bringing about spastic contraction of the vessels with increase in arterial pressure, thus indirectly leading to atherosclerotic changes. This was experimentally demonstrated by a great number of authors and recently again by K. Westphal. The lipoid changes in the bloodvessels are termed by Aschoff, atheroma. In the media of the vessels of the elastic type, there are mainly degenerative changes which consist mostly of lime deposits. Hyperplastic changes in the media of this type of vessels have thus far not been demonstrated during the early stage of arterial disease, nor have any such changes been seen in the adventitia.

In the large arteries of the muscular type, especially the large vessels of the extremities (femoral, tibial) and of the abdomen (celiac, superior and inferior mesenteric), the changes in the intima equal those encountered in the vessels of the elastic type, but here the changes in the media are much more pronounced. This was first demonstrated in the long vessels of the extremities by Virchow and by Monckeberg. They showed that in these vessels the calcification in the media far exceeded the changes in the intima. Other observers found the same changes in the muscular type of bloodvessels in the different organs of the abdomen. Kummel found them in the mesenteric and intestinal vessels; Schmiedel, as well as Staemmler, found these changes in the splenic and renal vessels.

The media in the muscular type of the smaller arteries and arterioles may be the seat of extensive fibrosis without any involvement of the intima. This is the well known arteriocapillary fibrosis of Gull-Sutton. In the arterioles the degenerative process usually predominates in the form of hyaline changes which are mostly confined to the intima and later spread to the media. The changes in the smaller vessels may be generalized, but in a large number of cases they are confined to one or the other organ. This explains why in some cases the symptoms are most outspoken in certain organs.

To recapitulate, the anatomical changes of arteriosclerosis are made up of two distinct processes, the hyperplastic and the degenerative. Both are to a certain extent dependent upon each other. As a rule both the intima and the media show changes, the degree of which may vary, at one time predominating in one layer and at another time in another layer. The changes in both layers are part of the same disease which we call arteriosclerosis and which Marchand terms atherosclerosis. E. Kaufman states that atherosclerosis must be differentiated from arteriosclerosis. Soft and mushy changes predominate in atherosclerosis, whereas, in arteriosclerosis, the calcified and fibrous tissue changes predominate. In the same artery both conditions may be present. The changes, either atherosclerotic or arteriosclerotic, determine the pathological consequences. Where softening predominates, aneurysmal formation, rupture, or dislodgment of emboli may result. If calcified and fibrous changes predominate, thrombosis frequently results. According to Huchard the senile vascular changes are atherosclerotic. In such an individual, while presenting symptoms of arteriosclerosis, the blood pressure remains low. In view of the fact that in all sclerotic vessels there are also fatty changes, L. Aschoff favors the term atherosclerosis.

In cases of simple hypertonia (essential hyperpiesis of Allbutt) the hyperplastic element predominates, which means there is a quantitative increase of elastic and muscular tissue of the bloodvessels, but qualitatively it is of the same good structure as the normal tissue. If the degenerative changes are demonstrable in connection with hyperplastic changes it may then be designated as true arteriosclerosis.

Although pathological studies have sufficiently demonstrated how frequently the vessels in the abdomen, especially those of the gastrointestinal tract, are affected by arteriosclerosis, the significance of this fact has not been sufficiently appreciated at the bedside. Virchow as well as Rokitansky have already called attention to that fact. Of the later pathological studies on arteriosclerosis of the gastric vessels the most valuable contribution is that of W. W. Hamburger, of Chicago, who worked in 1908 in Oestreich's Pathological Institute in the Augusta Hospital in Berlin. His studies comprised ten autopsies, five men and five women. Six patients were under forty-three years of age, the youngest being twenty-two. Two between the ages of fifty and sixty showed no sclerotic changes, and the other two showed very mild changes. Of the six cases in which the bloodvessels of the stomach showed extensive arteriosclerotic changes, Hamburger found those of the lesser curvature most frequently affected. The larger vessels of the submucous layer of the stomach were more frequently affected than the smaller ones. Hamburger's studies show that arteriosclerosis of the gastrointestinal tract may occur very early in life. Huchard, many years before, called attention to the same fact.

The factors bringing about arteriosclerosis may be indirect and direct. The indirect causes are chiefly the result of excessive functional demands on the bloodvessels. During the ascending period in life, the blood pressure and the tension in the arteries bring about an increase in the tone of the vascular wall, causing hypertrophy by an increase in elastic tissue (hyperplasia). During the descending period of life, the response of the vessels to the excessive demand cannot take place any longer by hyperplastic changes alone but by combined degenerative and hyperplastic changes. In some individuals this occurs earlier in life, in others later. That mechanical factors can cause arteriosclerosis is well demonstrated on autopsy material which often shows how general and local increase in blood pressure may cause early arteriosclerosis, as, for example, the arteriosclerosis of the pulmonary artery in case of congenital communication between the pulmonary artery and the aorta, in mitral stenosis, in chronic emphysema of the lungs, or extreme arteriosclerosis of the ascending aorta in stenosis of the isthmus of the aorta.

Increase of blood pressure in all the arteries in the body leads to general arteriosclerosis, as is well illustrated in secondary contracted kidney. Everyone, Romberg says aptly, gets his arteriosclerosis where the increased pressure changes are most marked.

The fact that the arteriosclerotic changes may be more marked in certain parts of the body than in others is well known.

As to the direct causes of increase in blood pressure the vasomotor apparatus undoubtedly plays a very important rôle. Physiologists and clinicians have for a long time appreciated the important part played by the vasomotor system in controlling the tonicity of the vessels and regulating the blood supply to the organs. It is only recently that the pathologists in interpreting the pathogenesis of arteriosclerosis and the causation of the symptoms, began to realize the importance of vasomotor influences in the causation of arteriosclerosis.

L. Aschoff in his latest excellent contribution on the subject states, "the mechanical overexertion of the vascular system brought about by infections or toxins is responsible for the irritation of the nerves supplying the bloodvessels and is the greatest factor in the pathogenesis of arteriosclerosis, because the nerves govern all these factors which etiologically come into consideration in the production of this disease."

The questions arise, why do some have a more irritable vasomotor system than others; why are the vessels in some more prone to arteriosclerotic changes, and why are some groups of bloodvessels in the body more affected than others? In answering these questions, a number of factors must be taken into consideration. In the first place, the status of the individual plays a most important rôle. It is well known that some persons are born with inferior vascular and nervous systems. The type known as the status thymicolymphaticus has usually a small heart and narrow vessels, in addition to enlarged thymus and enlarged lymph glands. This type of individual is, as a rule, less adapted to the demands the stress and strain of life puts upon him. During the first and part of the second decade of life he may be subject to skin manifestations in the form of eczema, urticaria and to frequent infections. Towards the latter part of the second decade and part of the third, circulatory disturbances may be present, such as cardiac palpitation, dyspnea on slight exertion and cold extremities. Idiopathic hypertrophy of the left ventricle, as described by Neusser, Osler and E. D. Friedman, is not infrequently present during that time.

Towards the end of the third decade the gastrointestinal symptoms manifest themselves, all of which are the result of vascular instability due to hypersensitiveness of the vasomotor system. The instability of the vasomotor system causes, in a great majority of cases, constriction of the affected bloodvessels, and if it affects large areas of the splanchnic system, the increase in blood pressure even during an early age may be considerable. In other cases vasodilatation is the predominating factor and the blood pressure is low. Wiesel separates status thymicus from status lymphaticus. The status thymicus is characterized by hypoplasia of all the organs, including heart and bloodvessels with predominating vagotonia. The vagotonia is responsible for vasoconstriction causing an increase in blood pressure. The vasoconstriction in some areas of the gastrointestinal organs may be so pronounced as to obliterate the small vessels and cause local ulceration. This has been proved pathologically by the studies of Roessle and clinically by the studies of von Bergman and his pupils in the causation of ulcer of the stomach.

The status lymphaticus type is also characterized by hypoplasia of the organs and enlargement of the glands, but there is predominating vasomotor dilatation with resulting low blood pressure. Bartel's status hypoplasticus type is characterized by narrow vessels without enlargement of the thymus or lymphatic glands. These individuals also have a tendency to spastic contraction of the bloodvessels which eventually leads to arteriosclerotic changes.

The influences which bring about hypersensitiveness of the vasomotor apparatus are manifold, such as chronic infection (syphilis), focal infection (diseased tonsils, teeth), intoxications (lead, nicotine, alcohol), metabolic disturbances (diabetes and gout), psychical trauma, internal secretion disturbances especially that of the suprarenals, or instability in the vegetative nervous system caused by internal secretion disturbances, or by changes in the electrolytes (kalium and calcium) as shown by the studies of F Kraus, S. G. Zondek and their coworkers. The influence of calcium ion on the constriction of the bloodvessels was conclusively demonstrated by Leites in the Physiological Laboratory of Pawlow. Leites transfused an animal with Ringer's solution without the calcium ion to which he added one c. c. of 1 to 1,000,000 or 1 to 10,000,000 of adrenalin solution and no narrowing of the bloodvessels resulted. If he added to this solution the normal quantity of calcium contained in the Ringer's solution, spastic contraction of the bloodvessels took place.

The importance of diabetes in the causation of vascular changes is illustrated by the frequent association in diabetes of thromboangiitis obliterans (Buerger's disease), gangrene, coronary spasm and coronary thrombosis. It must be remembered that affections of the smallest arteries and arterioles of the pancreas often associated with general arteriosclerosis may late in life cause diabetes as a result of degeneration of the islands of Langerhans.

The causative relation of the suprarenals to the vasomotor apparatus has been studied by Wiesel, Hedinger and others in reference to essential hypertension and to arteriosclerosis. There is no doubt that the suprarenals play an important rôle in certain cases of arteriosclerosis.

An important contribution regarding the influence of the vasomotor system on the bloodvessels was made by Staemmler. He showed that in some parts of the nervous system the sympathetic ganglia were the seat of chronic inflammatory changes. These were found mainly in elderly individuals and at times also in young persons. The inflammation of the ganglia preceded the arteriosclerosis and was not the cause of it as proved by the fact that in some cases inflammation of the ganglia was marked, although the vascular changes were insignificant. Staemmler states that inflammation of the ganglia may interfere with the peripheral vasomotor nerves and cause disturbances in the organs supplied by the vessels controlled by these nerves. It causes vasoconstriction and if such constriction persists it leads to arteriosclerotic changes and permanent increase in blood pressure. The inflammation of the sympathetic ganglia may be caused in turn by chronic in-

fections and intoxications. The vascular abdominal crisis of Pal, angina pectoris vasomotorica and angina abdominalis vasomotorica may thus be explained. In those cases of angina pectoris, endarteritis obliterans, or even in thromboangiitis obliterans where sympathectomy or cutting of the sympathetic ganglion has a favorable influence, it is likely that inflammation of the sympathetic ganglia may be the primary cause. Since the operation of excising the sympathetic ganglion for the relief of certain forms of angina pectoris is beginning to be in vogue, it is hoped that the pathological studies of the excised ganglia will determine whether the findings of Staemmler can be corroborated and possibly furnish definite indications for proper operative intervention.

Perez is of the opinion that spasmophilia plays an important rôle in causing vasoconstriction of the bloodvessels. Fleisher and Perez in their clinical studies showed that in this type of person ulcer of the stomach may develop as a result of persistent spasticity of the bloodvessels in the gastric mucosa.

From the above, it may be concluded that the activity of the vasomotor system is greatly responsible for the increased vascular tone; this in turn is caused by excessive functional demands made on the vascular system. The organs in the body most affected by the changes in the vascular system give rise to symptoms. At first, disturbances in the bloodvessels may be only of a functional nature (angioneurosis); later the changes in the vessels become permanent (angiosclerosis). During the angioneurotic stage the symptoms are mainly caused by psychical influences, whereas during the angiosclerotic stage the increased functional demand on the organs supplied by the affected vessels may bring about symptoms even in the absence of psychical influences.

The type of individual in whom the arterial changes are caused chiefly by the instability of the vasomotor system, is thin, tall, physically under developed with hypoplasia of all the organs including the vascular system and shows some or all of the manifestations of infantilism. There is marked epigastric pulsation and no pulsation can be detected in the suprasternal notch on account of narrowing of the aorta.

In contradistinction to the underdeveloped type just described, there is another type in whom the angiosclerotic changes are not as a rule preceded by angioneurosis. This type is the status apoplecticus. Arteriosclerosis in these cases is usually generalized with a tendency to predominate in the splanchnic vessels, especially if the individual is afflicted with plethora abdominalis.

By plethora abdominalis a condition is understood where there is persistent overfilling of the blood in the bloodvessels of the lower abdomen. This condition is encountered in the obese individuals who lead a sedentary life. It is a hereditary and constitutional anomaly in the majority of cases. In some cases it may be acquired by a sedentary mode of living and by overeating.

In the hypoplastic type referred to above the functional overwork of the bloodvessels causes spasticity and the resulting symptoms are due to local ischemia. In the type afflicted with plethora abdominalis the functional abuse of the bloodvessels is brought about by the fact that they are overfilled with blood which causes congestion of the organs they supply, thus leading to passive hyperemia at first, and later to active hyperemia and chronic changes in the organs proper. Enlargement of the liver and even spleen and heart are early manifestations. With the increase of local circulatory disturbances in the abdominal vessels there is an increase in the resistance in the splanchnic system as well as increased resistance in the smaller vessels and marked elevation in blood pressure.

In either type of subject, arteriosclerotic changes in the bloodvessels are not of the same character and severity throughout the entire body. In the smaller arteries of the gastrointestinal tract fibrosis may predominate; in other vessels calcification and ulceration are most marked. Sclerosis of the bloodvessels of the gastric mucosa, as shown by Hardt and verified by other pathologists, may play an important rôle in the causation of ulcer of the stomach and duodenum. Degenerative changes in the bloodvessels may cause aneurysmal formation, with subsequent rupture, or may lead to thrombosis. The same pathological changes are also encountered in the bloodvessels of the intestines, pancreas, spleen and liver.

It is understood that arteriosclerotic changes of all degrees of severity are not necessarily confined to certain types of persons. Harlow Brooks rightfully states that, due to stress and strain of our modern civilization, arteriosclerosis is the most frequent disease during middle life even in persons of normal status.

SYMPTOMS

In the hypoplastic type, in whom vasomotor instability is a causative factor, the gastrointestinal symptoms may be marked even during the angioneurotic stage. The symptoms, however, are vague and transient in nature, not characteristic enough to establish a diagnosis. The usual complaints are, fullness in the epigastrium soon after meals, nausea, capricious appetite, and at times aversion to food for weeks leading to considerable emaciation. The blood pressure may reach 140 and even 160, and sometimes rise as high as 180, due to nervous excitement. The blood pressure usually drops 20 or 30 mm. Hg. and more as the patient calms down in the course of examination. The blood pressure rises considerably after the subcutaneous injection of 0.5 to 1 c. c. of adrenalin (1 to 1,000) and may persist for two or three hours, gradually coming down to normal. That vasoconstriction may cause a lasting elevation in blood pressure can be demonstrated in the following way: If three of the extremities are bandaged tightly so as to obliterate the arterial pulse and the blood pressure is taken in the unbandaged extremity, an increase of 50 or 60 mm. Hg. is found, whereas in normal individuals the blood pressure under the same conditions is only increased about 5 or 10 mm. Hg. Localized repeated vasoconstriction of the gastric vessels, especially those supplying the submucosa, may lead to gastric erosion and even to ulcer formation with its attendant clinical symptoms.

The gastrointestinal symptoms in the plethoric individual are only present during the stage of angiosclerosis of the abdominal vessels and depend upon the degree of changes in these vessels and in the organs most affected.

If the arteriosclerosis involves mainly the abdominal aorta, it only causes distress in the epigastrium, annoyance as the result of continuous pulsation, and pressure tenderness over the abdominal aorta and slightly to the left of it. The pulsation over the abdominal aorta extends backward and to the left of the lumbar vertebra. There is also increased vascular tension in the arteries of the lower extremities as compared to those of the upper. The thickened abdominal aorta can be palpated in thin people. Ortner and Litten pointed out that there is a systolic murmur audible over the aorta in these cases, even if no pressure with the stethoscope is exerted; if pressure with the stethoscope is exerted, such systolic murmur is heard in a great many normal individuals. If the sclerosis of the abdominal aorta is due to syphilis, pain in the epigastric region is a marked symptom. The pain radiates to both sides of the abdomen and usually disappears when the patient lies down or even when he sits down. Aneurysm of the abdominal aorta is rare, but if present it gives rise to a great deal of pain, colicky in character, which appears periodically. The pain is confined mostly to the right of the abdomen. There is also a great deal of burning in the upper abdomen radiating to the lumbar region. Not infrequently, the pain is neuralgic in character, and the burning and tearing nature of the pain may persist day and night. The pain may come on at any time of day or night and lasts from ten to fifteen minutes and sometimes continue for an hour or two. At times it comes on one to two hours after meals and simulates gastric or duodenal ulcer. In these conditions food which causes distention of the stomach aggravates the pain.

At times the sclerosis causes narrowing of the abdominal aorta and its branches giving rise to diffuse generalized abdominal pain and pulsations throughout the entire abdomen. A loud blowing systolic murmur is heard in these cases over all the vessels of the abdomen. The vessels can be palpated, feel cordlike, and are tender to pressure. Meteorism is quite marked and according to Adolph Schmidt and his pupil, Kato, it is due to the failure of the intestinal tract to absorb the gases. The symptoms are usually attributed to some other gastrointestinal disease. The intake of food is cut down to a minimum by the patient, on account of the distress after eating, thus resulting in considerable emaciation and secondary anemia which arouse suspicions of malignancy, strengthened by the fact that the individual affected is usually of middle age, with a low or no gastric acidity. It is a well known clinical fact that as long as the arteriosclerotic symptoms are not confined to the digestive organs, the patient does not as a rule lose weight and usually appears perfectly healthy; in other words, if cerebral or thoracic symptoms predominate the patient's state of nutrition does not suffer.

If the sclerotic changes are most marked in the vessels of the gastric mucosa, localized trophic changes result causing distressing gastric symptoms. In these cases there is persistent pressure and pain in the upper abdomen independent of meals but aggravated by food. Nausea and loss of appetite are very marked and may lead to loss of weight. In cases of aneurysmal formation with subsequent rupture, severe uncontrollable gastric hemorrhages may occur. This is, however, rare. Rupture of arteriosclerotic vessels in the intestines causing intestinal hemorrhage is more common. According to G. Singer, intestinal hemorrhage due to intestinal atherosclerosis is characterized by the fact that it recurs very frequently and that the patients recuperate very rapidly. This is an important differential diagnostic sign from gastrointestinal bleeding due to cancer, varices from the esophagus or the stomach in the course of cirrhosis of the liver and gastric hemorrhages caused by thrombophlebitis in the splenic and hepatic vessels.

Arteriosclerosis of the abdominal vessels may give rise to periodic attacks of pain in the upper abdomen radiating to both sides and lumbar region accompanied by collapse and abdominal distention—the so-called angina abdominalis (Bacelli), angina epigastrica (Huchard) or angina subdiaphragmatica (Ortner).

(To be concluded)

Asthma with Pneumothorax

CHARLES A. SPIVACKE, M.D.
New York

Cases of asthma with pulmonary tuberculosis are not frequently observed. In examining charts of more than four hundred asthma patients, I found only four with pulmonary tuberculosis; of these four the sputum was positive in only two. Still more infrequent are cases of asthma with pneumothorax. This condition was discovered in the following case:

Case.—A. B., aged eleven, applied for treatment in June, 1923. Her previous history disclosed that she had had measles, whooping cough and pneumonia but at no time did she suffer from the symptoms which are usually associated with the onset of pneumothorax, such as sudden pain in the chest and abdomen, perspiration or faintness. Nor did close questioning reveal any loss of weight, daily elevation of temperature or night sweats. The asthma appeared for the first time following the attack of whooping cough when she was two years old. The paroxysms increased steadily in severity and frequency until she suffered from almost continuous asthma with cough and expectoration, which occurred mostly at night in her own home. It was further noted by the patient herself that any diet, which included some form of meat, would provoke an attack.

Examination showed her to be a well developed little girl, somewhat obese, and normal in all respects as to her eyes, nose, teeth, throat, heart and glands. The Von Pirquet test as well as urine and

sputum examinations were negative. Her lungs, however, showed sonorous and sibilant râles, and large rhonchi all over. The breath sounds were loud and could be heard at a distance, except in the upper lobe of the left lung. In addition to this there were other symptoms which indicated the presence of a cavity in the upper lobe of the left lung. On percussion a tympanitic sound could be heard posteriorly, and when percussion was done with a metallic object on a coin, placed over the left scapula, a metallic click could be heard with the stethoscope held a little below the left clavicle. An x ray examination on

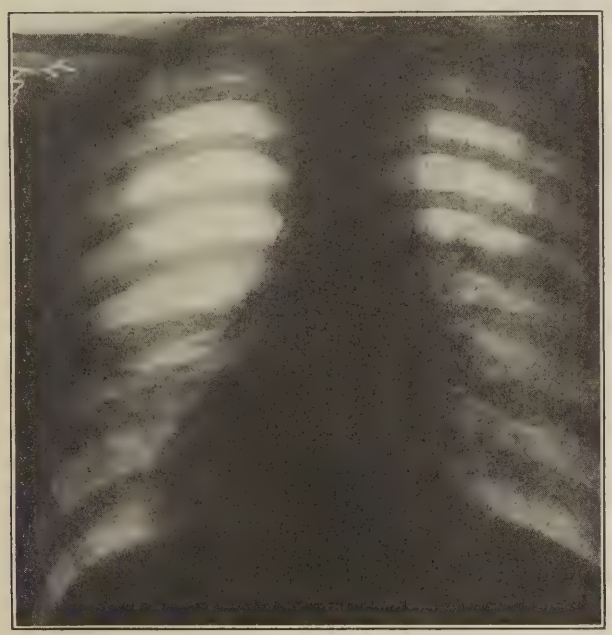

FIG. 1.—X ray examination made on October 18, 1923, showing a cavity of pneumothorax in left lung.

October 18, 1923, by Dr. Byron C. Darling, revealed in the right lung peribronchial thickening and fibrosis reaching well toward the periphery (Fig. 1). The left lung showed that the upper third was taken up by a large cavity of pneumothorax. The lower third of the lung showed aerated lung tissue with peribronchial thickening and fibrosis to a moderate degree.

She was tested with all the proteins and found sensitive to dust, horse dander, rabbit and goat hair, and beef. An investigation of her home disclosed that her bedding was stuffed with rabbit hair and goat hair. After a thorough cleaning of the house, silk floss was substituted for hair in the bedding and instructions were given to omit meat from her diet.

In July, 1923, treatment was begun with extracts of house dust and rabbit epithelium. Injections were given once a week and it was noted that her attacks became less frequent with intervening periods of several days of comparative freedom. After a few weeks, the attacks would occur on week ends only. Further investigation revealed that her meals during these periods contained considerable quantities of meat. Rigid instructions were again given to eliminate meat from her diet entirely, and with the patient's cooperation she has since been almost completely free from attacks.

Observation and treatment were continued all through 1923 and 1924. From June, 1923, until January, 1924, she had eight attacks, each one following as a result of her disobedience of instructions as to diet. During 1924 she had seven attacks of a mild character but she was at no time so distressed as to prevent her regular attendance at school. In the last five months she had had no attacks.

Frequent physical examinations were made and while the general condition of the patient showed marked improvement, still the cavity in her left lung persisted. The other physical signs, such as râles and rhonchi, were slowly disappearing and at times could not be heard at all. On January 15, 1925, x ray examinations were again made by Dr. Darling and Dr. Herman Mond and the findings indicated that the condition of her right lung was practically unchanged, there still being peribronchial thickening and fibrosis. The left lung showed throughout the upper two thirds, a cavity of pneumothorax with a clearly defined sac wall which was even larger than it had been sixteen months before (Fig. 2).

A physical examination at this time showed her to be generally much improved. The cough and expectoration ceased. She was much brighter and happier than at any time previously. Her lungs showed clear respiratory sounds and no wheezing râles could be detected. The breath sounds in the upper left lung were faintly audible.

COMMENT

From the history and the x ray findings in this case it can be safely concluded that the pneumothorax which gradually pushed the left lung downwards was not sudden in onset but that it developed rather slowly because of the rupture of alveoli produced by the strenuous coughing during the many years of continuous asthma.

The gradual development of the pneumothorax

FIG. 2.—X ray examination made on January 15, 1925, showing increase in size of pneumothorax.

will also explain the increase in the size of the sac as shown in the second picture of January 15, 1925.

From a general consideration of this case, it may be safe to assume that an early recognition of the allergic character of the disease might have prevented the pneumothorax in her left lung.

Clinical and Roentgen Considerations of Duodenal Ulcer

Including Some Newer Phases of Roentgen Interpretation

JOSEPH S. DIAMOND, M.D.
New York

ETIOLOGY

The pathogenesis of duodenal ulcer, as of all forms of peptic ulcer, still forms a chapter of speculative medicine. Rosenau's theory of infection as the primary etiological factor in the production of ulcer does not fully tally with experimental data. Infectious ulcers produced from bacterial strains derived from the bases of old ulcers are not analogous to the simple round peptic ulcer, but are multiple, hemorrhagic, sloughing ulcerations with a good deal of acute inflammatory reaction. In the consideration of the *modus operandi* in the infections, one cannot but regard the septic process as a secondary, contributory or exciting factor. There must be the necessary requirements, the *locus minoris resistentia,* that facilitates embolic processes in nonterminal arterioles.

In the light of our present knowledge, we must regard duodenal ulcer as a disease depending upon a constitutional derangement occurring in individuals who present some stigmata of inferiority, the result of an increased irritability or unbalance in the autonomic nervous system, associated with a disordered mobilization in the calcium ion. The functional vagus derangement, manifested by an augmentation of the secretion and an increase in the contractibility of the smooth muscle fibres, has been sufficiently substantiated by clinical and pharmacological data.

"The visceral tetany" characterized by a local contraction in the muscularis mucosa and large muscle fibres causes interference in the circulation, leading to ischemia, which in the presence of pepsin and a hyperacid chyme, readily leads to digestion of the mucous membrane and ulcer formations. Only under such a spastic state may bacterial invasion form emboli which result in peptic ulcer.

The predilection of ulcer to develop on or about the pylorus, the groove of Retzius at the lesser curvature, the cardia and last, but not least, the gastrojejunal stomata where specialized functions exist, further indicate the relation between excessive function and ulcer formation.

Recently there has also been gathered ample evidence to indicate the association of peptic ulcer with organic lesions in the medulla oblongata, as well as in the peripheral vagus trunks. Gustav Singer reports a series of ulcers in cases of chronic tuberculous basilar meningitis. Exner and Schwartzman found six cases of peptic ulcer in ten cases of tabes with gastric crises.

Direct lesions to the vagus trunks have also been described. These occur in thoracic tuberculosis, due either to pressure from a mediastinal gland or from the involvement of one of the branches from a pulmonary focus. The association of ulcer with pulmonary tuberculosis is frequently encountered by those engaged in this field.

Brief mention may be made of ulcer occurring in uremia, in severe skin burns, spoken of as Curling's ulcer, in skin lesions such as pemphigus, in chronic plumbism, in endocardial and other circulatory diseases, and finally, in mechanical causes such as pressure or blows. The thermic ulcer, spoken of by Mayo, while bearing some relation to gastric ulcer, does not enter into the consideration of the duodenal ulcer, the duodenum being too remote to be affected by the intake of hot foods.

We must therefore regard the constitutional element as the predominating factor in the pathogenesis of peptic ulcer, for otherwise how can one explain the frequent recurrences in the life history of an ulcer, whether at the old scar or at a new site, and also its recurrence even after surgical excision, unless the entire ulcer bearing area is removed by subtotal gastrectomy, when the site of predilection of the peptic ulcer is forever done away with?

CLINICAL SYMPTOMATOLOGY

We shall now pass from the field of hypothesis and enter upon the more productive soil of clinical symptomatology. Nothing is more fascinating in medicine than the art of eliciting from the anamnesis in the chronic gastric complaint, the subtle underlying pathology. One must learn to elucidate the important symptoms in the patient's history, and be able to cull from the maze of complaints, often irrelevant, the significant symptoms. We must learn from our legal confrères the art of cross examination, and the greater such art, the more important will be the data gathered from our patient. Too much emphasis cannot be laid upon the importance of the anamnesis, for, besides the roentgen ray, clinical symptomatology is the only means we possess to aid in making a proper diagnosis. The surgeon is often confronted with cases for laparotomy in which no laboratory data are obtainable. He is then obliged to rely solely upon the resources of his own art.

The one outstanding symptom that should make us consider a diagnosis of ulcer is pain that bears a definite relation to the intake of food. Without pain or distress, there can be no ulcer. All other symptoms, such as heartburn, pressure, fullness, and belching, are subordinate and carry no significance in the absence of pain.

The intensity of the pain will vary with the acuteness of the disease, the amount of inflammatory reaction, the degree of the ulceration, whether superficial or penetrating to the visceral coat or perforating through it, with the character of the food, and last but not least, with the type of patient, whether phlegmatic or hypersensitive. The pain may vary from a mere epigastric distress to a degree of severe intensity requiring an anodyne for its relief. Or without any premonitory symp-

toms, an acute perforation may take place and all the concomitant characteristics of such a perforation suddenly become manifest.

TIME OF PAIN

The pain in duodenal ulcer appears late, from two to four hours after eating. In the earlier stages

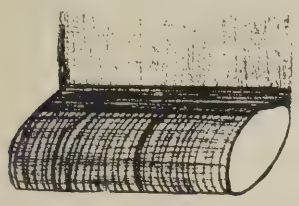

FIG. 1A

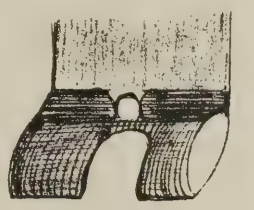

FIG. 1B

FIG. 1A.—Diagrammatic sketch of the muscular arrangement in the first portion of the duodenum showing the thickness of the longitudinal bundle of muscle fibres at the lesser curvature border and the attachment of the duodenohepatic ligament.

FIG. 1B.—Shows the mechanism of the muscular contraction in the presence of an ulcer at the lesser curvature.

it may make its appearance but once a day, usually in the late afternoon between four and five o'clock. As the disease progresses, the pain comes on with great regularity and punctuality with each meal, and also awakens the patient in the early morning hours between one and three o'clock. At first the pain may be characterized by a feeling of distention or oppression. Later, however, it assumes a boring, gnawing character accompanied by severe heartburn and waterbrash, the regurgitated material burning the patient's throat. The pain steadily rises in a crescendo fashion until either food, drink or soda bicarbonate gives prompt relief. The late pain in duodenal ulcer continues often into the next meal hour and gives rise to a sensation of hunger distress. The appetite is good and the severity of the hunger distress makes the patient take food frequently, with the result that most duodenal ulcer patients, in the early stages, appear well nourished. It is only later, when the pain is severe, that the patients fear the intake of food.

The pain of duodenal ulcer is referred upward under the ribs, and at times may be referred to the right nipple, but never to the shoulder or back. The pain of gastric ulcer is always referred to the left of the median line, and either to the back, to the left of the spine, or to the precordial region, depending upon the location of the ulcer, whether on the anterior or the posterior wall. At times it may simulate angina pectoris, and the case may present many difficulties of differentiation.

The night pains of ulcer differ from attacks of cholelithiasis by their lesser intensity, by their amelioration with changes in posture, and their prompt relief by the intake of either food or soda bicarbonate. The gallstone colic does not possess any of the previously mentioned characteristics, and usually requires morphine for its relief. Only in the old duodenal ulcer with pyloric stenosis does the pain and heartburn become agonizing in character, and is then only relieved by the induction of vomiting.

The influence of posture upon pain in ulcer is not sufficiently emphasized as a diagnostic aid, yet it often forms a pathognomonic sign. Some patients find relief by lying upon the left side, others by lying upon the abdomen, and still others by lying upon their backs, usually depending upon the location of the ulcer. Some will assume the supine or squatty posture. All these positions are protective measures to divert the irritating acid secretion from contact with the ulcer.

SUMMARY OF SYMPTOMS

To summarize the outstanding characteristics of pain in duodenal ulcer, we have:

1. The great regularity and punctuality of the pain, so that often patients can tell the time of the day by the onset of the pain.
2. Late pain coming on two to four hours after the meal.
3. Hunger pain.
4. Night pain.
5. Prompt relief by food or drink or alkali.
6. Amelioration by posture.
7. Pain referred to the right of the median line.

Moynihan epitomizes the sequence of events in duodenal ulcer in the following classical manner: 1, pain; 2, food; 3, comfort; 4, pain; and so on in a continuous cycle, while in the gastric type we have: 1, food; then 2, pain; and 3, comfort.

Another characteristic manifestation of the gastroduodenal ulcer is the periodical recurrence, usually in the early spring or late fall. However, it may recur at any time after a longer or shorter period of remission. The seasonal recurrence is dependent upon the increased irritability of the vegetative nervous system at these periods.

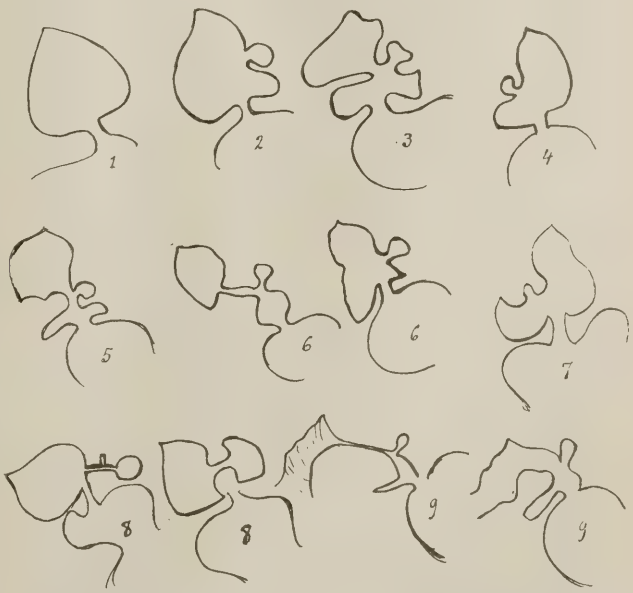

FIG. 2.—Tracings from actual cases indicating niches with their accompanying muscular contractions. 1, normal; 2, 3, 5, 6, 8, 9, niches on the lesser curvature, some after the administration of belladonna; 4 and 7, niches on the greater curvature.

GASTRIC HEMORRHAGE AND VOMITING

Gastric hemorrhage and vomiting, taught to be the two most important symptoms indispensable in the diagnosis of gastroduodenal ulcer, are found in the light of our new experience to be the least common. From the Mayo Clinic we learn that only

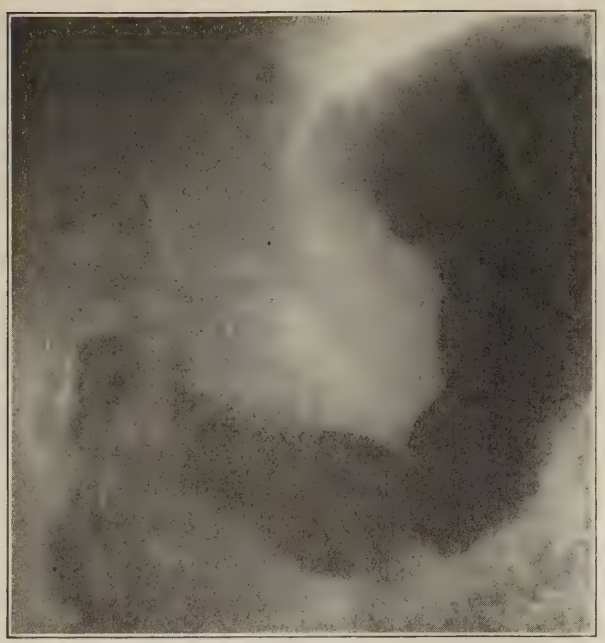

Fig. 3.—Niche at the lesser curvature border of the duodenum with retraction of the same border. Also spastic incisura at the greater curvature border in the plane of the niche. Operatively proved case.

twenty-five per cent. of all cases of hematemesis are due to ulcer; from Perry and Shaw only fifteen per cent., and Moynihan's statistics indicate that only ten per cent. of all gastric hemorrhages are caused by ulcer. The older teachings need revision, and the practitioner must erase from his memory certain facts which have been inculcated during his college days. In fact, Moynihan, speaking from the platform of the New York Academy of Medicine in 1919, remarked that, "In a case of gastric hemorrhage, consider all other conditions first, and last, peptic ulcer." We know now, thanks to the experience of the surgeon, that toxemias, and all forms of infection, such as gallbladder disease and appendicitis, are common etiological factors of gastric hemorrhages, not to mention gastric varices and gastritides. The term gastrorrhexis was introduced to indicate the obscure capillary bleeding from the mucous membrane of the stomach in the above mentioned conditions, the bleeding being seldom, if ever, found upon exploration. Gastric hemorrhage which persists and repeats itself frequently is usually indicative of a sclerosed and open vessel. Such bleeding cannot stop spontaneously, and therefore prompt surgical intervention is necessary if the life of the patient is to be saved. Melena is an important sign of duodenal bleeding. In the absence of the intake of bismuth or iron preparations, the appearance of a black stool signifies active duodenal bleeding. Physicians must be on their guard and always inquire into the character of the patient's stool.

VOMITING

Vomiting is encountered chiefly in pyloric stenosis, when the patient vomits large quantities containing food eaten the day before. The vomitus of such an ectatic stomach discloses the typical three layers of food, secretion and mucus. This stage, however, forms but a small minority of all ulcers. Vomiting is almost never found in the ordinary duodenal ulcer, which forms the great majority of all ulcers (eighty per cent.), unless in the late stages when it has become callous and causes stenosis. In the gastric ulcer of the lesser curvature type, vomiting is more common and is caused by the irritation of the food on the ulcerated area. It differs from the vomiting in pyloric stenosis by the early vomiting, the patient bringing up the food immediately after its intake. The vomiting in ulcer is associated with severe pain, the act of vomiting often giving complete relief. The dictum of Moynihan applies to vomiting more strongly than to gastric hemorrhage, for vomiting is present in almost any condition. Nevertheless, I have seen cases referred with a diagnosis of ulcer with all forms of vomiting, pregnancy not excluded. It is important to bear in mind that painless vomiting never occurs in ulcer.

PHYSICAL DIAGNOSIS

Physical examination offers nothing pathognomonic in the diagnosis of duodenal ulcer. Fluoroscopy has taught us that direct pressure upon an ulcer bearing duodenum frequently causes no pain. Tenderness is found only when the ulcer is in an active state of inflammation, with periduodenal changes. It is more commonly seen in the gastric type. It must be differentiated from the small epigastric hernia, which is always tender. The superficial hyperesthesia, the Head zone, the Boas tender point, the defense musculaire and the percussion tenderness are not sufficiently significant to help us in the diagnosis of duodenal ulcer. In gastric ulcer, however, the Boas tender point to the left of the lower dorsal spine is often encountered.

GASTRIC CHEMISTRY

The study of gastric chemistry as an aid in the diagnosis of peptic ulcer has received considerable criticism as to its utility. While it offers nothing pathognomonic, yet, if the test is properly conducted,

Fig. 4.—Characteristic functional defect at the greater curvature border of duodenum accompanying small funnelshaped niche at the lesser curvature side in the same segment. Operatively proved case.

sufficient data can be obtained that will enlighten us at a time when all other data are inconclusive. Rehfuss added a significant factor in the understanding of disturbed secretory physiology. The principle underlying his method, but not his technic, is worthy of consideration. The use of the Rehfuss tube is unphysiological and yields abnormal curves due to constant irritation of the tube. Erroneous results have made even Rehfuss pessimistic as to their value. I have convinced myself in numerous instances that the introduction of a tube in a fasting state can yield large amounts of a hyperacid secretion if kept up long enough. It is my custom to extract the gastric contents twice, one after the hour period and then again after the hour and a half period, using the ordinary tube.

In a study of 158 cases of duodenal ulcer, I found in sixty-two per cent. high acidities, between 40 and 90 free hydrochloric acid, and in eighty-two per cent. of these the free acidity rose during the second hour. Also, there was an approximation between the free acid and the total acid. Lastly, there was a marked hypersecretion in the second extraction (Table I).

In gastric ulcer, no such tendency to a late rise in the acid curve is seen. In a study of twenty-six cases I found, in the main, acidities which did not exceed the normal, and often gave low normal figures.

OCCULT BLOOD

Occult blood in the gastric contents carries less significance than in the feces. The slightest gagging of the patient causes capillary trauma to the mucous membrane of the stomach, particularly in the gastritides. Also swallowed discharges will interfere with the test.

The presence of occult blood in the feces, when the examination is carried out under proper precautions, is significant. There are too many factors of safety, however, which minimize the value of the test. The patient must be on a meat free diet for three days. Precaution as to bleeding gums, hemorrhoids, or any other anorectal bleeding is to be observed. Such extreme care can only be followed in an institution.

THERAPEUTIC TEST

Before finally passing from the chapter on the clinical consideration of duodenal ulcer, I must mention the socalled therapeutic test which is a corroborative diagnostic test. Any simple ulcer, if placed upon a Sippy or any other medical form of treatment, responds promptly with a complete cessation of all symptoms. This *eclatant* manner of the response to treatment is pathognomonic of ulcer. No other condition can show such a sudden cessation of all symptoms.

RÖNTGEN DIAGNOSIS

In the röntgen ray we possess today the greatest aid in the correct diagnosis of duodenal ulcer. Cole's studies on the duodenal defect made the diagnosis of postpyloric or duodenal ulcer possible in a larger percentage of cases and helped to establish the validity of the direct method of röntgen diagnosis.

The indirect method of röntgen diagnosis which is dependent upon functional disturbances has failed to supply even its staunchest adherents with more

FIG. 5.—Niche on lesser curvature of the duodenum, visualized only after complete relaxation of the duodenum by administration of belladonna and several days restriction to milk diet. Operatively proved case.

than presumptive evidence. Only the late manifestations met with in stenosis, such as gastrectasia, with intermittent deep gastric peristalsis and retention, can be regarded as immutable evidence of an organic lesion. This disturbed physiology is but an end result. The early symptom group of rapid motility, exaggerated peristalsis, increased tone, are common to many conditions and are dependent upon the increased irritability of the autonomic nervous system. They are present in simple vagotonia, in the psychoneurotic and psychotic, and in achylia gastrica. They arise also reflexly from diseases of other abdominal viscera such as the gallbladder, appendix and colon. They can be readily compared to the clinical symptom group of fullness, pressure, pyrosis, belching, and water brash, which are common in so many functional and organic diseases arising from intragastric and extragastric causes, not excluding even such remote conditions as tuberculosis, myocarditis, coronary disease, and interstitial nephritis. These group symptoms in themselves have no significance unless correlated with a definite clinical entity. Röntgenologically, as well as clinically, the indirect signs merely help to draw attention to an existing lesion without particularly specifying its character or location.

The direct method of Cole was the first attempt to interpret duodenal ulcers on direct evidence of changes taking place in the duodenum. The morphological differences, however, between a duodenal and a gastric ulcer, representing a filling defect in one and a pouching or niche in the other, were not clearly understood for some time. Cole attributed the filling defect on the duodenal contour to or such as induration of the ulcer or a traction in the walls of the duoder

later drew attention to the functional spastic phenomena in the wall of the duodenum in the segment of the ulcer, which also produced filling defects. The terms employed, therefore, such as duodenal "defect" or "deformity" are unspecific, as they do not make clear the actual pathology taking place in the duodenum.

Akerlund's (1) recent studies on the mechanics of the duodenum have shown that the röntgen deformities of duodenal ulcer consist in a combination of organic and functional changes and that the predominating component of the duodenal deformity is due to a functional spasm. His ability to compare a large series of operative cases with the röntgen findings aided materially in the elucidation of the röntgen deformities and in the correct interpretation of duodenal ulcers. He found that the most constant röntgen manifestation of the duodenal ulcer was a niche which was present in sixty per cent. of his series, and that the niche was accompanied by functional deformities which were analogous to the gastric incisures occurring in the plane of the ulcer, these always disappearing under anesthesia.

In the latter part of 1922 I undertook studies of a series of cases (2) with the object of making a close analysis of the various components of the röntgen deformities of duodenal ulcer, and particularly to study the frequency of niches. Forty-two cases were thus examined. It was found that the duodenal deformities were seldom due to organic changes and seldom represented the ulcer base proper, but were chiefly due to the associated muscular contractions accompanying the ulcer. By the [illegible]smodic measures, the duodenal wall [illegible] and under the röntgen ray such [illegible]ed in intensity or disappeared al[illegible] and niches which were not seen before became apparent. These muscular contractions can be readily compared with the intense blepharospasm in corneal ulcers or with cecal spasms in tuberculous ulcerations of the cecum where the surrounding musculature contracts tightly about the ulcer bearing area as a protective measure, and does not permit the entrance of foreign or noxious substances. When, however, the spasm is relieved, and such patients are reexamined with the pylorus and duodenum in a state of complete relaxation, then niches or ulcer pockets similar to gastric ulcers can be readily visualized. In our series, twenty-eight cases, or 66.6 per cent., could be interpreted as niches.

TABLE I: DUODENAL ULCERS

25	50	40	60				

A series of forty-nine cases in which the gastric contents were examined at the end of the first hour and during the second hour. In thirty-nine cases, the acidity increased or remained the same during the second hour. In ten cases the acidity decreased.

METHOD TO RELAX THE DUODENUM AND PERMIT THE FILLING AND VISUALIZATION OF THE NICHE

In order to facilitate the filling of the niche and at the same time differentiate the spastic from the organic deformity, I have employed a routine method of reexamining the duodenum in a relaxed state.

This method is as follows: After the preliminary röntgen examination, the patient is administered twenty to twenty-five drops of tincture of belladonna every four hours for forty-eight hours, simultaneously restricting the diet to milk; at times even alkalies may be necessary. A marked relaxation of the pylorus and duodenum then ensues, the duodenal lumen is considerably widened, the spastic contracture of the greater curvature is lessened or may entirely disappear, and a niche which was not seen before often makes its appearance on the lesser curvature.

CLASSIFICATION OF THE RÖNTGEN DEFORMITIES IN DUODENAL ULCER.

The röntgen deformities of duodenal ulcers may be classified as follows: 1, niche; 2, defect; 3, bulb retraction; 4, diverticulum formations. They may occur either singly or in a combination of any or all of these.

The niche.—The niche may represent any stage of pathological change in the duodenal wall from a simple, nonindurated mucous ulcer to the penetrating and callous ulcer. Its filling and visualization are dependent upon the degree of irritability of the surrounding musculature. The slight constriction of the muscularis mucosa gives to the niche a flaskshaped appearance (Figs. 2, 3 and 5). If, however, the irritability is too intense, then the entire musculature surrounding the ulcerbearing area is puckered up, as has been mentioned, in a state of undue contraction, not permitting the contrast substance to enter the ulcerated area. With this method of relaxation, the filling of the ulcer pocket becomes greatly facilitated. Out of the twenty-eight niches visualized, twenty-two were on the lesser curvature, five on the greater, and one was an enface niche.

The functional deformities which accompany the niche are analogous to those found in the gastric ulcers of the lesser curvature type. They are, however, more constant and more pronounced on account of the greater irritability and small size of this organ. These deformities are, 1, incisura or segmental contraction, appearing usually on the greater curvature opposite the lesion; 2, a puckering contraction in the immediate vicinity of the niche, mostly found on the lesser curvature.

Duodenal defect.—A filling defect of the duodenum may be caused by, 1, organic changes such as induration, cicatricial contraction, adhesion or tumor; 2, functional changes such as spasm which are due to muscular contractions, the circular muscle fibres being drawn up toward the stronger longitudinal fibres on the lesser curvature side (Fig. 2). The contractions may be so intense that the lumen of the duodenum is reduced to the diameter of a match stick or thread.

The organic defects are rare, are usually situated on the lesser curvature side, are irregular in outline and are constant in size, while the spastic defect is rounded in outline, is broad and possesses smooth borders, and is usually found on the greater curvature side in the plane of the ulcer (Figs. 3 and 4), or at times at the base of the duodenum. They can be differentiated by the method above described when the functional defect is lessened in size or made to disappear completely, while the organic filling defect remains unchanged.

Bulb retraction.—Retraction of the duodenum is another form of spastic contracture and is caused by the contraction of the longitudinal bundle of muscle fibres on the lesser curvature side. It always surrounds the base of a niche. The retracted side appears shortened and drawn in, giving the lesser curvature border a concave appearance (Figs. 3 and 4). This bears some analogy to the gastric retraction which is occasionally seen in the saddle ulcer resulting in the snail form or tobacco pouch stomach, when the lesser curvature is shortened and curled upon itself.

Diverticulum associated with duodenal ulcer.—The diverticulum consists of a pouching of a portion of the duodenal wall situated in close proximity to the ulcer. They may be often mistaken for niches and can be differentiated by their ability to contract, changing their contour from plate to plate. They are always situated proximal to the ulcer, and their place of predilection is the basal portions of the duodenum.

CONCLUSIONS

In the röntgen interpretation of the duodenal deformities, an effort must be made to recognize the actual lesion taking place within the duodenum and express it from a pathological and anatomical standpoint. We must differentiate between a niche, infiltration, scar, and spastic contracture. Errors will be eliminated if one will follow a definite plan and apply himself to study minutely the character of the changes in each border, always bearing in mind the pathological entities which affect the duodenum and the manner in which they express themselves under the röntgen ray.

The indirect method is vague, indefinite, and confusing. It is dependent upon nervous phenomena and not upon the direct evidence of pathology in the duodenum. At its best, it leads but to presumptive evidence.

While the direct method is more painstaking, requiring serial radiography and greater technical accuracy, as well as finer interpretative study, its results are, however, positive.

A Plea for Early Operation in Diseases of the Gallbladder*

M. E. BLAHD, M.D.
Cleveland, Ohio

Notwithstanding a voluminous literature and an ever increasing experience, there seems to be no unanimity of opinion regarding the operative indications for diseases of the gallbladder and bile tracts. Some recommend early operation, others recommend late operation, and still others are utterly opposed to operation. Some advise operation during the acute attack; others would wait until the acute attack had subsided. This diversity of opinion upon the subject is so great that a perusal of the literature only tends to confuse the reader. The solution of this problem lies, in determining definite operative indications, such as exist in appendicitis, in order that the family physician, with whom lies the responsibility of making a decision for or against surgical consultation, and who also frequently must make the final decision for or against operation, may have something definite upon which to base his opinion.

The present chaos in biliary disease is, at least in part, attributable to the multiplicity of its clinical manifestations, to an underestimation of the importance of infection and to the seeming impossibility of determining universal operative indications to meet the requirements of all the various phases of this trouble. The fact that some of these patients recover spontaneously after the initial attack, adds to the existing confusion. This recovery, however, in most instances is only apparent, the infection lying dormant, prepared to flare up at the slightest provocation and to give rise to a fresh attack.

At operation, all types of biliary disease are seen, ranging from simple inflammations of the gallbladder and bile ducts to the severest forms of gangrene with perforation and general peritonitis. Frequently the infectious process extends to the neighboring organs, producing adhesions between the gallbladder, the pylorus, duodenum and omentum, and also causing inflammation of the gastrohepatic ligament, the head of the pancreas and the retroperitoneal lymph space. The contents of the gallbladder, besides cal-

*Read before the Cleveland Academy of Medicine, September 15, 1922: from the Surgical Service of Mt. Sinai Hospital.

culi, some of which are always impacted in the neck of this organ, are either cloudy bile, thin or thick pus and mucus. As the amount of inflammatory exudate increases, the gallbladder becomes more and more distended, until it seems as though it must burst. The pressure upon its walls is tremendous, and according to the laws of hydraulic pressure, equal in all directions. Little by little the neck distends, until the impacted stone floats up into the fundus and permits the escape of the bile, calculi and infected material, into the cystic and common bile ducts.

After the gallbladder has discharged its contents into the deeper bile passages, the cystic orifice closes and one of the calculi remaining in the gallbladder is again firmly impacted into the gallbladder neck. Only in this way can the presence of calculi in the common duct be explained when there is complete occlusion of the cystic duct. If, however, the calculus is so firmly impacted in the cystic orifice, that it resists all attempts to float it up into the fundus, the pressure from above, accompanied by the most excruciating pain, millimetre by millimetre, slowly but surely, dilates the cystic orifice and duct to such an extent that frequently the cystic duct joins the common duct with a centimetre wide opening. After a passage has been established, the gallbladder discharges infected material and calculi into the common duct and duodenum. Some of the calculi and infected material generally remain in the common duct and cause infection, obstruction and dilatation of this organ, creating a situation fraught with the gravest danger for the patient. Here again, infection is the determining factor, aided and abetted by the calculi. But the calculi, although playing an important and most serious part, are of secondary importance, the primary rôle is played by the infection. If it were not for the infection, there would be no calculi except in the occasional instance of the sterile cholesterin stone. When once calculi are present, and when one of them, as usually happens, obstructs the cystic orifice, the natural forces of the individual are then unable to bring about a complete cessation of the infectious process, and it is only a matter of time before the disease becomes chronic, invades the neighboring organs, and provokes the most serious complications.

Before proceeding with the consideration of common duct infection, a condition which is practically always preventable, let us pause for a moment to analyze the situation. Is it possible to determine operative indications which will permit of surgical intervention in time to avoid the life endangering and crippling conditions such as have been described above? If the premise, which has been maintained so far in this article, that infection is the causative agent in all types of inflammatory biliary disease, is correct, it naturally follows that this same agent must act as a guide to the determining definite operative indications. That infection is a treacherous agent needs no further proof. Especially is this true if the infection is located in a concealed portion of the body, as in the gallbladder and the appendix. In these situations it is difficult to observe accurately its progress with the result that it may develop further, insidiously but irresistibly, until a serious crisis, in which the very life of the individual is at stake, is brought about. In the case of the appendix, this danger has long been recognized, and after many years of embittered strife and hectic argument the school of experience has taught us not to procrastinate but to operate as soon as inflammation of the appendix is diagnosed. In other words, the moment that appendicitis is definitely recognized, it becomes a surgical disease. However, in gallbladder disease, because the apparent danger does not appear so urgent, the tendency is to regard it less seriously and delay operation. Nevertheless, the same danger exists; only, in this instance, it is not generally recognized. Of course, it may be argued with propriety that the immediate danger of cholecystitis is less frequently as threatening as that of appendicitis, but this fact is more than offset by the remote complications occurring weeks, months and even years later, leading to chronic invalidism and finally death. Perhaps the danger approaches more slowly, but it comes on just as surely, yet the immediate danger of acute cholecystitis is by no means negligible and is probably much underestimated as attested by a number of cases occurring in my experience.

Case I.—S. O., male, came to my office on July 8, 1914, complaining of excruciating pain in the right upper abdomen. His past history was not important, except for slight attacks of indigestion from which he had suffered for many years. The present illness began about one hour previous to his coming to the office. At this time he was seized with severe pains which steadily grew more severe until they became almost unbearable. A hurried examination revealed the patient in severe shock with marked rigidity of the entire abdominal wall. A diagnosis of perforated abdominal viscus was made and the patient sent to the hospital for immediate operation.

Operation revealed a perforated gallbladder. This attack was the first from which this patient had ever suffered and bears out the statement made above that serious complications may arise even during the first attack.

Case II.—H. S., female, aged fifty-nine, entered Mt. Sinai Hospital on December 2, 1922, complaining of severe abdominal cramps. For the past twenty years she had suffered from repeated attacks of pain in the region of the gallbladder. Her present illness began on the day before with severe pain in the region of the gallbladder accompanied by vomiting. During the ten days previous to her admission to the hospital she was never free from pain.

Examination by me on the second day after admission to the hospital disclosed a typical case of cholecystitis. Immediate operation was advised but refused. On the following day, on account of increased severity of the symptoms, consent was obtained for operation. At operation a perforated gallbladder was found. This case strikingly substantiates the belief that even a short delay may prove most serious to the patient.

A search of the surgical records of the hospital revealed other cases of a similar nature but the two cases cited above are sufficient to illustrate the point that immediate danger in cholecystitis is a positive quantity and must always be reckoned with.

If it were possible to determine definitely, without jeopardizing the welfare of the patient, which cases of cholecystitis will end in recovery, without serious

complications, a conservative attitude might be adopted with a feeling of security. But since this is not possible, as our everyday clinical experience clearly shows, only one course is open, and that is to remove the offending gallbladder while the disease is still confined within its walls, and before it has had opportunity to cause perforation or peritonitis, or to invade the deeper bile passages. At only one time can this be accomplished with certainty, and that is, as soon as the diagnosis of cholecystitis is made. Even a few hours' delay may bring in its wake the most serious consequences. The same axiom that applies to appendicitis also applies to gallbladder disease, namely, that cholecystitis, upon recognition, immediately becomes a surgical disease.

Undoubtedly many cases of gallbladder disease will end in recovery without operation; also, in a great number of acute appendicitis cases the patients will recover without operation. This fact, however, does not deter the surgeon from removing the appendix, for fear that conservative treatment might be instituted in the wrong case. Why then should this reason prevent us from instituting the same rational and radical treatment in the case of the gallbladder? It is equally as impossible to distinguish between those cases of cholecystitis which will end in recovery of their own accord and those which will not, as is the case in appendicitis. Therefore, to avoid serious consequences, the same principle which acted as a guide in the former case must be adopted here. In the hands of those skilled to operate upon gallbladder disease, the mortality in early operation will be no greater than in appendicitis, and the results will be equally as good.

Stones in the common duct! Truly a sad chapter —sad especially, because, in most instances, it is a preventable condition and its occurrence must be attributed to a faulty understanding of the underlying pathology upon which gallbladder disease is based. Unfortunately, however, there will always be instances of common duct involvement, just as there are instances of gangrenous and perforated appendices due, no doubt, to certain mitigating circumstances beyond one's control. The family physician can do much to prevent the occurrence of this most serious condition, if he bears in mind the maxim, that a diseased gallbladder should be removed while the disease is still confined within its walls.

There are two clinical types of common duct involvement. In one, the individual is in apparent good health; he has neither fever, icterus, nor acholic stool. He is able to attend to his duties and only occasionally has a slight attack of indigestion, or a mild cholangitis attack accompanied by a slight icterus and a trivial elevation of temperature. His common duct is filled with calculi, but not completely obstructed. Bile, in sufficient quantity to maintain its function in the process of digestion, and to prevent jaundice, reaches the duodenum. Frequently, invoking the aid of numerous gallstone cures, he remains fairly comfortable for a period of years. However, the final day of reckoning always comes, and here again infection is the determining factor. On account of added infection or an acute exacerbation of the ever present inflammation, the duct becomes completely occluded and immediately gives rise to those most alarming symptoms so characteristic of common duct obstruction. The other type is acute from its very inception. There is severe pain, marked pyrexia, high grade icterus, chills, and acholic stool. In an incredibly short time the patient suffers great loss of weight, frequently forty to fifty pounds. His condition immediately becomes critical. Under these circumstances there is no longer any hesitancy on the part of anyone in recommending operation to meet this contingency. A fatal mistake, however, is frequently made, by delaying operation in the main hope that the patient's condition will improve or for fear that the patient may not be able to stand the shock of operation. Yet instead of improving, the patient grows worse from day to day, yes even from hour to hour, and the longer the operation is delayed, the less chance is there for recovery. Immediate operation, before the patient's vitality is completely sapped by torturing days and nights of pain, chills, high fever and inanition, offers the only chance of succor.

The dangers of instituting operative procedures during an acute attack of cholecystitis and cholangitis have been greatly exaggerated. In my experience and also that of my associates, who have operated during the acute attack for a considerable time, such danger is found to be no greater than operating during an acute attack of appendicitis. As has been stated above, delay may cause irreparable damage, and even if the patient escapes with his life, late operation or operation after the acute attack has subsided, greatly lessens his chance of ultimate cure.

The choice of operation depends upon the conditions which are found when the abdomen is opened. If there is empyema of the gallbladder, marked pericholecystitis and peritonitis, drainage should be instituted and the gallbladder removed at a secondary operation. If, however, the disease is still confined to the gallbladder, cholecystectomy is the operation of choice, providing there are no insurmountable contraindications, such as technical difficulties and complicating diseases. Probing of the common duct through an infected gallbladder is to be condemned on account of the danger of infecting the duct. This is especially true if the cystic orifice is occluded. It is better to incise the common duct directly if there is any doubt regarding the presence of stones.

CONCLUSIONS

Thus, on the basis of the pending date, the following conclusions are reached:

1. Infection is the determining factor in cholecystitis. The calculi are only of secondary importance.
2. Cholecystitis is a surgical disease.
3. Choledocholithiasis is a complication of cholecystitis, and is preventable in the vast majority of instances.
4. In cholecystitis the choledochitis operation should be performed during the initial acute attack. Waiting for the acute attack to subside may endanger the patient's life, give rise to serious infection of the neighboring structures, and always greatly lessens the chance for an ultimate cure.
5. Cholecystectomy is the operation of choice for cholecystitis, but if there are contraindications to its performance, cholecystostomy should be substituted.

Psychosis Following Surgical Operations

A. L. SORESI, M.D.
New York

I wish to direct attention to a distinct clinical entity that can be called psychosis following surgical operations. Practically all patients operated upon present symptoms more or less severe and of varying duration, which show that a derangement of the mind existing prior to the operation has been increased. I shall not dwell here on what could be called the mild temporary psychosis following all surgical operations, done either under general or any form of local anesthesia, or of the psychosis following a condition that has caused an evident disturbance in the whole system, such as an acute intestinal obstruction, a fractured skull, an exophthalmic goitre, or other conditions, or of psychosis preexisting, and only aggravated by the surgical operation.

I shall give consideration only to those conditions observed by every surgeon, whereby normal, or apparently normal, patients show a derangement of the mind after surgical operations; real psychosis following surgical operations. I believe that this condition represents one of the least known and most serious complications following surgical intervention and many patients have been lost, who could have been saved, had their condition been properly interpreted and treated.

In fact, every surgeon has observed patients who from few to several hours after the operation show a marked change in their psychic condition, some becoming exceedingly restless and even violent to the point of having to be restrained by the straitjacket, others, on the contrary, showing a complete apathy, indifference to everybody, even to their dearest relatives, and to everything. The patients may lie perfectly still for periods of time varying from a few minutes to several hours; they may utter meaningless words, remove their coverings, try to get out of bed, look blankly at people surrounding them, and again fall back to perfect stillness and indifference. Although the patients may have been extremely clean and proper before operation, one may notice saliva dripping from their mouths, they may urinate, move their bowels in bed, without their knowledge, and remain indifferent and without discomfort in filth. At times a most dramatic incident occurs: the patient jumps out of a window or otherwise commits suicide or attempts to end his life. The condition of these patients may improve spontaneously or following haphazard medication: often it becomes worse and the patient is lost. In any event the surgeon and the internist called in consultation offer, at the best, the vague explanation that the condition may be due to postoperative shock or some indefinite toxic absorption.

The treatment of this condition is generally wholly inadequate and based on wrong principles, as is illustrated, for instance, by the administration of morphine, bromides and other drugs intended to quiet the patient, who instead, as will be shown later, might need the administration of stimulants.

Below I report three cases,[1] observed in the last few years, previous to the time in which instead of attempting to cure these patients we instituted a preventive treatment. We do not report cases observed during a previous period when we did not consider these patients as true cases of postoperative psychosis, because my experience is similar to that of other surgeons, and therefore of no particular interest.

I believe that postoperative psychosis is a clinical entity, distinct from any other condition. What characterizes true postoperative psychosis is the fact that *pulse, temperature, respiration and all other functions are normal at the onset of the psychic symptoms.* We insist on the words: "at the onset of the psychic symptoms," because at a later period disturbances more or less severe and often fatal will naturally ensue. But we emphasize the fact, on which a differential diagnosis must be based, that at the onset of the psychic symptoms, pulse, temperature, respiration and all other functions are normal. By normal we mean conditions that are considered normal, after surgical operations, as, for instance, a temperature of 101° or even 102° or 103° could not be called abnormal after an operation for an acute condition in the abdomen.

Pathogenesis.—The patients, whose cases I have reported, were all normal, or apparently normal, five of them having been examined in consultation with competent neurologists, so that the psychosis could not have arisen from a latent condition that manifested itself after the shock caused by the surgical operation, because all these patients were normal again in a few hours, we would dare to say (at the most, after three days) and remained normal. These cases, therefore, could reasonably be classed as cases of true postoperative psychosis. But the words postoperative psychosis do not mean anything unless we study why the operation should be followed in a comparatively small number out of the many in which surgical operations are performed, by a psychosis that, in at least three of our cases, we feel sure would have been fatal, if not properly interpreted and treated. There must be some factors that play an important part in the development of psychosis after a surgical operation that are not inherent to the operation itself, but to the individual patient. Indeed, it seems that the type and severity of the operation had little to do, *per se*, with the manifestation of the psychosis, because if we observed such psychosis in a case where a very extensive and difficult procedure, such as the removal of about three quarters of the stomach and a corresponding amount of the omentum, was resorted to, we have also noticed the same phenomenon in a case of simple appendectomy, which was performed in a few minutes and certainly caused little trauma and shock. It also seems that infection in these cases was not a factor, *per se*, because out of the six cases only one patient had a septic peritonitis; all the

[1]This study included three additional cases which have been omitted for lack of space.

others had normal temperatures and no infection, before the time of the manifestation of the psychosis or after. The anesthetic also seems to be a factor of not great importance *per se,* as far as quality and the amount of anesthetic used. Ether was used in one case and gas and oxygen in two (in the case of cancer of the stomach the anesthesia lasted about one hour and a half); local anesthesia (one spinal, the others infiltration) in the other three.

In these cases we have to exclude absolutely some of the factors that are commonly known to cause psychosis after a surgical operation, such as the removal of any important endocrinic organ, because in only one case (ovarian cyst) one such organ was removed. This patient, however, was past the menopause and the ovary had been completely destroyed by the pathological condition, so that the removal of the cystic ovary could not have caused any endocrinic disturbance. Nor can we blame the crushing of important and abundant tissues, or direct injury to the nervous system, or preoperative or postoperative infection, only one patient having any temperature; or intoxication from any special medication, as used to follow the extensive use of iodoform gauze; or autointoxication, that follows ileus or intestinal obstruction. Perhaps the only case in which there might have been an evident direct cause is the one patient accustomed to cocaine and morphine.

These patients, however, have all something in common: they were normal individuals who underwent an operation more or less severe; a psychosis developed soon after the operation, but not immediately; they were accustomed to some kind of drug, namely, one patient to cocaine and morphine, the others to alcohol, tobacco, coffee and tea; they were benefited by strychnine; they were normal again after a few days. That the psychosis followed the surgical operation and that it developed soon after the operation, but not immediately, there can be no doubt; that the patients were normal before the operation, and were normal soon after and are still normal seems also to be a positive fact, therefore I feel justified in classifying these cases as true postoperative psychosis.

Two important points must be considered: the patients were accustomed to some drugs; they were cured by strychnine. The mild drug habit, which seems to be the causative factor in the development of postoperative psychosis must be interpreted broadly. A person does not need to be an actual drug fiend in order to be influenced by and feel the effects of some drug. We may go a step further and assert that all the staple foodstuffs and mildest drink contain some substances which stimulate the activities of the organism as actual habit forming drugs do. It is only a question of degree of stimulation and habit forming that differentiates them. In fact, take away his dry or smoked fish from a Northern European or his spaghetti from the Southern Italian and their capacity for work, nay their health, is impaired. And returning to actual drug habits, who is not under the influence of some drug nowadays? Coffee, tea, chocolate, tobacco, are not yet on the prohibition list and are consumed daily in tremendous quantities by practically everyone. Alcoholic beverages have been, in the past, consumed legally in great quantities; at the present time only their quality seems decreased.

It seems reasonable to suppose that patients who are accustomed to the stimuli received by certain foodstuffs and especially by the socalled mild drugs, such as coffee, tea, chocolate, tobacco, alcohol, may suffer psychically when suddenly deprived of such stimuli as occurs after a surgical operation. This explanation of the pathogenesis of postoperative psychosis is important, because as far as we know due attention has never been given to what can be called mild drug habits as found among the civilized man of today, as the causative factor. It seems reasonable to think that the anesthetic, trauma and shock caused by a surgical operation, although in the greatest majority of cases not sufficient to unbalance the nervous system, might do so when the patient's nervous system is accustomed to the use of some drug, of which he or she is deprived after the operation, at a time when it is needed most. This explanation seems rational because we have not observed in children or young adults, the manifestation of such cases of psychosis as the ones described. Young people have not had time to contract any habit which might have affected in some way their nervous system.

Treatment.—The treatment of these cases, we believe, presents also an interesting subject for discussion. If the manifestation of the psychosis is due to the need of some drug, a need accentuated by the shock and trauma caused by the operation and the anesthetics, it would seem logical to think that the direct administration of the drug to which the patient was accustomed should be specific. It would seem logical, therefore, to inquire of any patient who has to undergo a surgical operation if he or she is accustomed to any drug, whether alcohol, coffee, tea, tobacco, morphine, cocaine, or any other, and administer such drug in small quantities as a preventive of the possible manifestation of a psychosis, or better be on the lookout, and give it immediately at the first manifestation of the psychosis. It is to be remembered that in cases of emergency this inquiry may not be possible, and we believe that in strychnine we have a valuable drug that will help the great majority of patients, especially the ones accustomed to tobacco, which obviously cannot be allowed in many cases immediately after the operation. (In a recent case we allowed a patient to smoke cigarettes on the evening he was operated upon, under local anesthesia for appendectomy. The patient who was accustomed to smoke an excessive number of cigarettes daily was very restless but was almost immediately quieted after smoking. Strychnine was also given hypodermically.)

I should like to emphasize that in these cases we must be practical: no matter how bad and unhealthy the patient's habits these habits should be restored as soon as possible, if the patient shows any sign of suffering from their interruption. Remember, a cripple will run faster and more securely with the most primitive crutches to which he is accustomed, than with the most perfect artificial limb recently applied. The moment this cripple had to walk far and fast for his safety would be the most inopportune time to make him change his old crutches for the most ideal artificial limb. The same principle applies to pa-

tients: after a surgical operation, when they have to walk fast and sometimes very far in order to recover their health, they need their habitual stimulants no matter how bad, as the cripple needs his old crutches. Bad habits may be reformed after complete recovery from the surgical operation. To be more specific, smoking should not be forbidden unless actual damage may ensue from it: tea, coffee and alcohol, if not allowed by mouth may be administered temporarily by rectum, although we realize how poor a substitute the rectum is for the one who craves for a drink of wine, whisky, coffee or tea.

The value of strychnine in these cases seems to be beyond discussion. We feel sure that in at least three cases without the aid of strychnine the patient would have been lost, and the same opinion was shared by all the doctors who have seen these cases. The value of strychnine seems to be due to the fact that this drug is indicated in cases of depression or functional nervous atony of the nervous system, when organic diseases are not present; that it greatly relieves the patients who are in surgical shock, acting as a stimulant, when the vasomotor centre is only depressed, as seems to be the case in patients suffering from psychosis due to the need of some drugs to which they are accustomed.

I do not advocate the use of strychnine as a preventive, because it would stimulate and excite the nervous system which would naturally become so much more susceptible to the trauma, shock and intoxication caused by the surgical operation and the anesthetic. Also it would be unwise to give strychnine to all patients who are delirious or distressed after a surgical operation, because all the patients who are distressed or delirious are not suffering from a psychosis. Naturally these patients must be treated *secundum artem* and the strychnine reserved for cases of true psychosis.

CASE I.—A. D. R., female, forty-six years of age. Nothing interesting in the family or personal histories except that patient suffered from pain in the lower abdomen during the last five years, especially for a few days preceding and following menstruation and was very nervous during the menopause. Patient was operated upon (spinal analgesia) for voluminous ovarian cyst of the left side which had completely destroyed the ovary. The night preceding the second day after operation patient began to be irrational and from a refined lady was changed into a woman using the vilest language and insulting everyone around her. Nothing abnormal could be detected in her physical condition except a slight increase and weakening of the pulse. Her condition became rapidly bad and the patient was so restless and exhausted herself in vain efforts to jump out of bed, and attempts to throw things at people surrounding her, that in the afternoon the pulse had become frequent and thready. Patient vomited twice during the late morning and early afternoon. Washing of the stomach was attempted, but could not be carried out. Morphine had been given hypodermically, without any result. Strychnine, one sixtieth of a grain, was administered at 10 a. m. and such injections repeated every eight hours. The results were extremely gratifying. Patient rested for short intervals during the night, slowly regained consciousness and was perfectly normal two days later. In this case it was found that the patient was a great tea and coffee drinker.

CASE II.—C. A. M., professional man, fifty-four years of age. Nothing interesting in the family or personal histories, except that the patient had suffered from typhoid fever eight years previously. Patient was operated upon for cholelithiasis (local anesthesia—novocaine one to three hundred). The operation was not difficult, although quite numerous and dense adhesions complicated the removal of the gallbladder. The patient was rather comfortable during the early part of the night, later began to be restless and the following morning decidedly irrational, trying to get out of bed, asking for his clothes, seeing people threatening him, talking meaningless words, and then falling into profound collapse. Patient was given morphine hypodermically at first symptoms of restlessness, but became so much worse rapidly that the family was notified as to the very serious condition. Pulse was only slightly weaker and more frequent than normal, 105°, temperature always around 100° and respirations around 24. Nothing could be detected to account for a condition that was threatening the life of the patient. Injections of strychnine, one sixtieth grain, were given hypodermically around 9 a. m. At 2 p. m. a friend of the patient, calling to see him, told me that perhaps it might be important to know that the patient in the last year was addicted to not only morphine but also to cocaine. Cocaine and morphine were immediately injected hypodermically; strychnine was repeated at 9 p. m. The patient was quieter in the evening and slept from 8:30 p. m. to 10 p. m. When he awoke, he was still irrational, but greatly improved, and out of immediate danger. I ordered another injection of morphine and cocaine at 2 a. m. and kept up the same treatment, strychnine, morphine and cocaine for three days. Patient improved steadily and was completely rational on the third day after the operation, and remained rational, making an uneventful recovery and later undergoing a successful treatment against the drug habit.

CASE VI.—Male, aged sixty-six. Operated upon (gas and oxygen) for extensive abdominal adhesions. Began to be slightly irrational the day after the operation. Strychnine was given immediately, as in the other cases, and patient was completely rational again on the fourth day after the operation. This man, an Italian, was accustomed to drink wine and to smoke rather heavily, and we feel that the strychnine prevented the manifestation of a graver psychosis than in the other cases.

CONCLUSIONS

It seems reasonable to conclude that, a, postoperative psychosis is a true separate clinical entity; b, as its pathogenesis, what may be called a mild drug habit plays an important rôle; c, in such cases strychnine is almost a specific; d, before submitting a patient to a surgical operation, we should make inquiries about his habits, habit forming drugs, coffee, tea, alcohol, tobacco, special foodstuffs, and give whatever patient was accustomed to; e, the habits, bad or good, of the patient should be restored as soon as possible after the operation; f, since we have followed this plan we have been fortunate in preventing psychosis as serious as the ones reported.

Chronic Prostatitis With Special Reference to Its Focal Aspects*

JACKSON K. HOLLOWAY, M.D.
and WILLIAM H. VON LACKUM, M.D.
Rochester, Minn.

Chronic prostatitis has become a subject of particular interest on account of its apparent relation to focal infections. With the advance of knowledge concerning foci of infection, and diseases and symptoms resulting therefrom, the prostate gland is rapidly being assigned its legitimate place with infected teeth, tonsils, eroded cervixes, and so forth.

As early as 1815, Lognean described chronic inflammation of the prostate as a complication of gonorrhea. In 1836, Lallemand called attention to lesions in the prostate and seminal vesicles as being responsible for certain nervous and mental symptoms. In 1838, Verdier described the pathology of prostatitis. Thompson, Finger, Fuller, Guyon, Albarran, Young and others have also contributed to our knowledge of this subject.

ETIOLOGY

Although gonorrhea is the initiating cause of chronic prostatitis in the majority of cases, organisms borne through hematogenous and lymphogenous routes may also be causes. Prostatitis may develop within days or weeks following acute urethritis, or certain systemic infections. On the other hand, years may elapse before the definite chain of symptoms becomes prominent. It is likely that gonorrhea is responsible for only seventy-five to eighty per cent. of the cases. Of 1,627 patients with chronic prostatitis, diagnosed in the section on urology, Mayo Clinic, between the years 1922 and 1924, 1,239 (76.2 per cent.) admitted having had gonorrhea, while sixty-five (three and nine-tenths per cent.) gave indefinite histories, or else pleaded ignorance of having had it. Three hundred twenty-three (19.9 per cent.) did not give a history of having had gonorrhea.

Influenza, pneumonia, typhoid fever, measles, septicemia, and other infectious diseases are apparently definitely responsible for a certain number of cases, particularly cases in which chronic passive congestion of the posterior urethral adnexa has been present for some time. McCrae and others equally familiar with the subject assert that prostatic infection is not always specific; that it may arise from organisms in the blood, or urine, or neighboring structures. The rich blood supply and the numerous lymph passages in this region support this contention.

In cases of chronic prostatitis in which there is a definite history of gonorrhea the gonococci are seldom found on examination of the prostatic secretion. Thomas says that it is agreed that except in the acute catarrhal forms, the gonococci are demonstrable in only fifty to seventy-five per cent. of the cases in the first year, in fifteen to fifty per cent. in the second year, in five to ten per cent. in the third year, and that they are rarely found after this, provided reinfection has not occurred. Hogan claims that by repeated cultures, the gonococci may be demonstrated several years after infection. He reports one case in which the organisms were recovered eight or nine years after the original infection.

No single organism can be regarded as specific in the production of chronic prostatitis. Janes and Thomas call attention to the large number of diphtheroids as the predominating organisms. These are often intracellular, and closely resemble diplococci. It is possible that they have been mistaken for gonococci in some cases reported many years after the appearance of gonorrhea. In a series of 118 carefully selected cases, Player, Lee-Brown, and Mathé found Bacillus coli in twenty-four cases and hemolytic streptococci in thirteen. Cultures were sterile in fifty-seven cases. Hitchins and Brown assert that in forty-six cases Staphylococcus albus was cultured in twenty-seven; Staphylococcus aureus in eleven, nonliquefying cocci in thirty-four; streptococcus in twenty-seven; diphtheroids in thirty-four; colon bacillus in two, and gonococci in five. Tano found that in repeated cultures in thirty-four patients various aerobic and anaerobic organisms were present in twenty-four.

Although the foregoing citations do not cover the field of investigation in such cases, they demonstrate the variety of organisms that may be found. Apparently the initiating organisms do not remain

*Submitted for publication March 31, 1925.

alone, but secondary invaders enter. Gonococci die within a comparatively short time, as a rule. However, having invaded the territory they set up certain conditions of lowered local resistance, which predispose to invasion by various other organisms. This being true, it may be assumed that all types of chronic prostatitis are essentially alike and that it is unnecessary to attempt to differentiate postgonorrheal and nongonorrheal prostatitis. It is for this reason that the infected prostate may be included in the list of socalled infectious foci.

As exciting factors in the production of prostatitis may be mentioned excessive physiologic or abnormal sexual indulgence, exposure to cold, bicycle and horseback riding, or other influences causing prolonged congestion of the sexual organs. In rarer instances trauma seems to be a factor.

PATHOLOGY

Follicular, parenchymatous, interstitial, and periprostatic forms of prostatitis are recognized. These terms are quite descriptive. A clinical classification equally descriptive includes atrophic, hypertrophic, parenchymatous, interstitial, and cicatricial types. If the process develops through infection of the urethra the portion of the gland nearest the urethral canal is most frequently affected. Moreover, it tends to be segmental; that is, the infection is most marked around certain groups of glands. In certain cases suppuration develops. Endoglandular proliferation and desquamation of the epithelium lining the acini take place. Inflammatory infiltration and sclerosis of periacinous stroma may follow. In other cases the glandular elements may be replaced by fibrous hyperplasia. There is usually a combination of lesions of the parenchyma and stroma, varying in degree in different areas. Some acini are dilated, and frequently contain epithelial cells, leucocytes and bacteria; others are collapsed, or are replaced by fibrous tissue.

CLINICAL SYMPTOMS

In general the symptoms of chronic prostatitis may be divided into three general groups: urinary, sexual, and general.

1. In this group the most common urinary symptoms are burning on micturition, frequency, nocturia, slow stream, cloudy urine, urgency, hematuria, urethral discomfort, and shreds in the urine. These symptoms often occurred singly. In many, however, sex and general symptoms are included among the complaints.

2. The group presenting chiefly sexual symptoms is rather large. Table 1 illustrates the type and relative frequency of some of the symptoms.

In certain cases only one or two symptoms may be manifested, in others, several. The degree of the infection apparently does not always determine the number or severity of symptoms. In many cases, because of the close connection between the sexual apparatus and the central and sympathetic nervous systems, direct relation seems to exist between nervous stability and symptoms.

3. Mental symptoms, ranging from worry (usually sexual) to melancholia and despondency, are common. Occasionally the patient commits suicide. Two of our cases fall into this group. A number of the socalled male sex neurotics are victims of definite prostatitis, which manifests itself not only locally, but often generally, through its very definite effect on the nervous mechanism of the patient.

7	Symptoms falling into two or more of the foregoing groups, special emphasis on none	168	142	10.8	26	7.7

Malaise; dull, ill defined headaches; general weakness; various aches and pains around the groin, perineum, or suprapubic region, head, back and legs; indolence; and so forth, are frequently the major symptoms in cases in which the prostate

gland is not suspected as being infected, and the source of definite symptoms.

DIAGNOSIS

The history of former urethritis should always direct attention to the prostate. Palpation of the prostate by rectum may be of aid in establishing a diagnosis. Usually in cases in which infection has followed the urethral path the gland is somewhat enlarged, irregular, and asymmetrical. It is not particularly sensitive, and it is often difficult to express secretion. When infection is of hematogenous origin the gland may feel normal in size or slightly enlarged. It is usually smooth, regular and symmetric. Sensation is frequently increased; and abundant secretion may be readily expressed.

Digital examination alone is insufficient; it is, moreover, a common cause of error, and usually fails to give a definite idea of the degree of infection. In a series of 1,627 cases of prostatitis, the gland was abnormal in 1,222 (75.1 per cent.). Four hundred fifteen (24.9 per cent.) of them were diagnosed as normal, following digital examination. These proved to be abnormal following provocative stimulation and repeated examinations. Thus it appears that, even in clinics in which the examination and investigation of the prostate gland remains in the hands of men familiar with urological conditions, reliance on a digital examination alone means failure of diagnosis in one fourth of the cases investigated.

By far the most accurate means of diagnosing prostatitis is microscopic examination of the secretion. The presence of an unusual number of pus cells means definite infection. In many cases an increased number of leucocytes and a corresponding decrease in the lecithin content of the secretion are found on primary examination. It is advantageous, often necessary, to subject the patient to provocative stimulation and repeated examinations in order to establish a diagnosis and determine the degree of the infection. Cases are graded according to the number of pus cells in the secretion:

Normal secretion contains 1 to 5 pus cells to each high-power field
Secretion with infection 1— 5 to 15 pus cells to each high-power field
Secretion with infection 2— 15 to 50 pus cells to each high-power field
Secretion with infection 3— 50 to 150 pus cells to each high-power field
Secretion with infection 4—150 and more pus cells to each high-power field.

The presence of small clumps of pus cells is practically always diagnostic. Such infection, however, may be latent, and several stimulating provocative treatments may be required to prove its severity. One or more small clumps of five to ten or more pus cells detected on examination of the secretion should immediately arouse suspicion. Frequently in cases with no other indication of infection a single cluster of pus cells invites further investigation, and repeated examinations disclose high-grade infection. Notthafft holds that often pus does not appear until after repeated massages, and further that at times pus does not make its appearance until after as many as fifteen massages of the vesicles.

The use of the Kollman dilators and silver salts is apparently of great aid in making a diagnosis within a comparatively short time. We are now employing a provocative procedure more or less as a routine in cases submitted for investigation, particularly in cases in which there is an apparent focal systemic condition, but in which all other foci have been definitely excluded, and cases in which there is a definite deviation from normal sexual or urinary function or findings. This procedure is similar in some respects to that described by Player and Mathé. It consists in carefully dilating the posterior urethra (usually 35 to 40 F.) by means of a Kollman posterior dilator, and then instilling one-half to one per cent. solution of silver nitrate into the posterior urethra with a Guyon catheter. A preliminary examination of prostatic secretion is made prior to instrumentation. Secretions are then examined at daily intervals over three to five days. Three or four examinations are usually sufficient to give a good idea of the degree of infection present, although more may be required. It is rarely necessary to repeat the dilatation, and never oftener than three days. Ordinarily, no harm results from such manipulation, provided gentleness and care can be exercised.

In a few cases dilatation and the instillation of silver nitrate seem to be contraindicated. In these cases the patients are, 1, feeble old men; 2, highly sensitive and intolerant men; 3, men presenting symptoms of definite hypertension, active pulmonary tuberculosis, lowered body resistance, subacute infection of the epididymis, and 4, those in whom the initial examination of the prostatic fluid discloses highgrade infection. In such cases a modified procedure should be employed. The use of a moderate sized sound and the instillation of protargol or argyrol solution to the posterior urethra may be sufficient. Massage, dilatation and instillation of a solution of silver salts seem of definite value in hastening diagnosis, and make it possible to estimate the degree of infection within a very few days. Any concession to the vigor of the provocative procedure will entail a proportionately long period of time for the estimation of the degree of infection.

It is probable that many diagnosticians and especially those who discourage the use of Kollman dilators, will hold that this method is too vigorous, and suggest that infection is initiated in some of the cases in which abundant purulent secretion is ultimately found after a negative primary finding. There is no proof of this. In more than two thousand five hundred cases examined by these methods we have had no reason to believe that the provocative method caused infection, or a more severe grade of infection than could have been proved by a sufficient number of repeated examinations of prostatic secretions, massage alone having been employed. To assure ourselves of this, we have investigated the cases in which a negative diagnosis was given at various times after provocative stimulations. Of the 124 cases examined between July and September, 1924, in which a negative diagnosis was made, one hundred were subjected to provocative stimulation, and repeatedly examined. In no case did the number of pus cells increase appreciably following manipulation. If no cells, or only occasional cells were found at the original examination, none or only occasional cells were found on subsequent examinations. In one case dilatations and fourteen examinations of the prostatic and vesicle fluid failed

to reveal pus cells in the secretion. In sixty-one of the 124 cases there was a history of gonorrhea having been present within from one to forty years. Forty-one of these patients were subjected to the provocative procedure. In another series of cases of functional impotency repeated prostatic massages and instrumentation failed to produce evidence of prostatitis. In this group, twenty treatments were the average.

In isolated cases there has been slight bleeding, pain, or general reaction following instrumentation. Bleeding seldom occurs, provided the proper care has been observed in introducing the instrument, and if dilatation has not been carried beyond the limit of tissue elasticity. We have found the use of local anesthetics in the urethra unnecessary in the majority of cases. When it is desirable to eliminate the possibility of disagreeable sensation or pain the instillation of five c.c. of two per cent. butyn solution (Abbott), or two per cent. procain solution, is sufficient. Satisfactory anesthesia is produced by butyn solution within four or five minutes; procain requires a considerably longer time, and is less effective.

Reactions seldom occur. The patient should be given a hot sitz bath and be placed in bed for several hours following urethral manipulations. Reactions have not been observed except in cases in which a very definite prostatitis has been diagnosed on primary examination, and in which an attempt was made to determine the severity of the process. However, in such cases reactions may follow simple prostatic massage. Such reactions are practically identical with those seen in certain cases following cystoscopic examinations or catheterization. In many cases in which cystoscopy has been followed by reaction, examination of the prostatic secretion has revealed the presence of pus cells in large numbers. It is suggestive, at least, that many reactions seen in males following urethral instrumentation are due to prostatic infection.

Subsequent findings in examination of the prostatic secretion, and clinical improvement in general metastatic conditions observed with surprising regularity, warrant our deduction that provocative stimulation is a valuable procedure when the prostate is a possible source of infection, and massage fails to express secretion containing pus cells. In certain types of cases it is warmly recommended as being the method most likely to produce a true diagnosis of the condition of the prostate gland within the shortest period of time. Included in these types are, 1, cases in which there is a history of gonorrhea without recent prostatic treatment; 2, cases of abnormal prostates, namely, asymmetry, size, sensation, or consistency; 3, cases in which urologic conditions are abnormal, such as especially asymptomatic pyuria, pyelonephritis, persistent cystitis, or sexual complaints that may be due to some infection; 4, cases presenting remote general symptoms that may be due to a focus of infection, and 5, cases in which the initial examination of prostatic secretion reveals clumps of pus cells, or granular or degenerated leucocytes.

In old men, however, there is an increase in leucocytes, and the presence of degenerated cells and debris is not uncommon. The significance of such findings in the prostatic secretion of men more than fifty must be judged according to the individual case. Darget says that chronic prostatitis in old men may be an entity associated or not associated with hypertrophy and that the two conditions are frequently confused.

TREATMENT

The routine treatment of prostatitis is fairly well understood by urologists, and patients should be referred to them in order to obtain the best results. The chief procedure consists of prostatic massage at regular intervals of from two to three days, and followed by an intraurethral instillation of argyrol (five per cent. aqueous solution). The ureter is dilated with sounds or Kollman instruments as indicated by the number of pus cells in the secretion, and the persistence of urinary symptoms. When the pus cells decrease, dilatation and stronger application of silver salts are employed. The employment of these methods at frequent intervals facilitates expression of secretion, stimulates absorption, and increases the patient's resistance to overcome the infection. Diday irrigations are employed frequently if chronic posterior urethritis complicates the condition. If the vesicles are involved along with the prostate, which often happens, the same general methods are employed, but the vesicles are also stripped with a vesicle stripping instrument. Hot sitz baths, short rectal douches, and constitutional measures, are also employed.

In cases in which there is pain, or in which the condition is especially stubborn, aolan (a nontoxic, nonbacterial nucleoalbumin), ten c.c., is injected intramuscularly three times a week. In many cases this apparently hastens improvement in local as well as in general symptoms. It has proved of most advantage in cases of arthritis in which the infection of the prostate and vesicles seemed to be the focus responsible for the condition. The best results come from treatment carried out in courses.

From four to eight weeks is the usual time required for a course of treatment, and a rest period of several months should follow the course. During the rest period systematic hydrotherapy is beneficial. During the interval of treatment, or after the second or third course, the infection is usually reduced to a low minimum. A recheck at subsequent periods of several months is advised, and indications are decided on for or against further treatment, depending on symptoms and whether the infection remains at a minimum, or deviates upwards.

There are few contraindications to treatment. In brief they are: 1, acute and subacute local and general conditions; 2, marked hypertension; 3, cases in which operation has recently been performed; 4, cases in which there has been an exhausting illness; 5, senility and inanition; 6, marked neurosis with no positive evidence of very definite infection; 7, malignant conditions which will prove fatal within a year; and 8, local urethral or rectal conditions which contraindicate manipulations.

Unless the case is definitely surgical operation is discouraged. Palliative treatment in most cases is satisfactory and should be the method of choice in dealing with these cases.

RESULTS

Cases of prostatitis and vesiculitis, if of long duration, are rarely cured. In most of the cases presenting symptoms referable to disease of the prostate gland systemic and prolonged local treatment will improve the patient's local and general condition. In our series only five per cent. failed to show some definite improvement. In practically all cases showing no local or general improvement it was found that other factors were probably responsible. Usually failures could be attributed to, 1, the presence of other septic foci; 2, local urethral conditions, or infection involving structures beyond the prostate and vesicles, and 3, a complication of diseases in patients with poor resistance. In some of the cases treated, particularly the early cases, the results were striking (Table 4).

TABLE IV

GENERAL RESULTS

	Cases
Chronic prostatitis	1627
Treated	771
Investigated and diagnosed only	856
Treated, definite improvement	731 (94.8 per cent)
Treated, no improvement	40 (5.2 per cent)

	Cases
Improvement graded 1, after average of 21.01 treatments	91
Improvement graded 2, after average of 22.53 treatments	303
Improvement graded 3, after average of 25.82 treatments	320
Improvement graded 4, after average of 24.75 treatments	17
Improvement of any grade received an average of 23.72 treatments	

Of the 323 nongonorrheal cases, 155 were treated; 168 were diagnosed only. In some of these, local improvement was not noted until other septic foci were removed. Results from local treatments, however, seem identical with those in patients giving a history of previous gonorrhea.

It is estimated that thirty-five per cent. of all males have some degree of prostatitis (13). We have positive objective and subjective evidence that an infected prostate gland resulting from gonorrheal or nongonorrheal invasion very frequently serves as an active focus of infection. Others have pointed this out previously. However, the symptoms are frequently so ill defined that the prostate is overlooked, while other infected foci are dealt with in the hope of ameliorating the patient's condition.

It is possible that there is some relationship between the prostate and other infectious foci, such as teeth and tonsils. What this relationship is remains to be proved, but it is suggested by the large number of cases of infected prostates without a history of genitourinary disease. In our series of patients with prostatitis, 225 had definite periapical infection of the teeth; 361 had definitely enlarged and questionable tonsils; 190 had tonsils which were diagnosed as definitely septic; and 291 had periapical infection and questionable types of tonsils. In many instances removal of teeth or tonsils did not relieve symptoms. In some instances the symptoms cleared readily on treatment of the prostatic condition without interference with infected teeth or tonsils. In another group relief followed attention to all foci.

In male patients more than sixteen, whose symptoms might possibly be dependent on a focus of infection, the prostate gland should be subjected to careful and systematic examination. Simple rectal palpation of the gland is not enough; the prostatic secretions should be examined also. Stained smears, cultures and animal experimentations do not seem to be necessary to diagnose prostatitis, although further investigation along these lines is warranted.

CONCLUSIONS

1. The prostate gland is infected in a large percentage of males, many of whom have no history of gonorrhea.

2. Prostatic infection is frequently responsible not only for numerous local and general symptoms, but for conditions classified as focal in origin.

3. Prostatitis may be latent, and if so, can often be diagnosed only after repeated examination of prostatic fluid subsequent to provocative stimulation.

4. By provocative stimulation we may usually estimate the degree of prostatic infection within three or four days.

5. Systematic treatment of prostatitis and vesiculitis, consisting of a few urologic procedures carefully and vigorously and systematically carried out, is simple, and in most instances is followed by definite improvement.

REPORTS OF CASES

Case I.—A man, aged twenty-six, came to the clinic April 29, 1922, complaining of pain in the feet. In December, 1920, apparently without cause, he became rather ill with fever and a slight chill, developed pain in the feet and knees, and had a urethral discharge. He was in the hospital for six weeks, and could not walk well for four months. The diagnosis at this time was gonorrheal rheumatism. Treatment consisted of prostatic massage, urethral injections, and vaccine. A recurrence in 1921 was treated similarly. On March 15, 1922, there was another recurrence with pain in wrists and fingers. On admission there were no urinary or sexual symptoms.

The Wassermann reaction and examination of the urine were negative. The hemoglobin was 78 per cent.; the leucocytes numbered 7,600. Tonsils 2, contained fluid pus; röntgenograms of the teeth revealed periapical infection 4, and of the feet bilateral calcaneal spurs. The prostate was small, smooth, regular, and firm; the vesicles on the left were infiltrated and both highly sensitive; the urethra was normal.

From April 26 to May 25, 1922, twenty-five local treatments were given; May 24 tonsillectomy was performed. Symptoms were all relieved before the tonsillectomy. July 14, the patient returned and could not walk on account of acute arthritis of the feet and ankles. From July 14, 1922, to May 17, 1923, 114 treatments were given and fifteen injections of gonorrheal glycerol vaccine were administered. Findings were negative on examination May 17, 1923. No signs or symptoms were evident.

Case II.—A man, aged forty-one, came to the clinic July 22, 1924, complaining of pain in the legs of eight years' duration. The pain was mild at first, but progressive. It was intermittent, occurring once in from three to four weeks, lasting from a few days to four weeks, and was not localized to any particular part of the lower extremities. Aspirin afforded relief. There was a history of gonorrheal infection fifteen years before, with complications in the left epididymis, but apparently cured in six weeks.

(*To be concluded*)

Renal Function Determination Aided by the Use of Sodium Salicylate Intravenously*

A. STRACHSTEIN, M.D.
New York

The advent (1) and development (2) of the phenolsulphonephthalein test has no doubt been the most valuable addition to the armamentarium of renal function determination. Its simplicity of application and the comparative ease of its interpretation have at once made it popular, so that it is now the most widely used test, especially in this country.

In reviewing the literature upon renal function tests, one is, however, impressed with the fact that no single test is absolutely reliable. One must use a combination of tests in order to gather reliable data. Thus Pepper and Austin (3) report a case, that of a boy of nineteen in whom twenty-five urinary examinations were made during a period of over three months in which the boy was under observation. He never failed to show a large amount of albumin, two and seven tenths to eight gr. to the litre, and at the same time an exceedingly large number of hyaline, granular, fatty and epithelial casts, free fat droplets and much renal epithelium. They used the dye twice, as follows:

1. a. Phenolsulphonephthalein: Elimination after one hour, fifty per cent., after two hours, seventy-one per cent.
   b. Phenolsulphonephthalein: (Two weeks later, but within the three months' period of observation). Elimination after one hour, sixty-seven per cent., after two hours, eighty-two per cent.
2. Indigo carmine was used once and was seen at the ureteral orifices in six and four minutes.

Both these functional tests showed, therefore, unusually prompt elimination. Other similar cases were reported by these authors in the same paper. They conclude that in some cases of nephritis although an impairment of sodium chloride elimination begins to show, the phenolsulphonephthalein test is usually prompt.

Baetzer (4) draws the following conclusions:

1. There exist cases of well marked nephritis with evidence of impairment of renal function in which certain tests reveal an eliminative power or even above normal.

2. He describes cases from which he concludes that there may be a stage in nephritis when hyperpermeability exists at least to phenolsulphonephthalein and some other substances with an elective impermeability for chlorides as suggested by Widal. He further concludes that it is necessary to study renal function from the viewpoint of a considerable series of functional tests rather than to draw conclusions from the excretion of any one drug. Piersol (5) is of the opinion that the phthalein test is of little value in the early diagnosis of nephritis, since deficient phthalein output does not occur until evidences of renal disease are recognizable by ordinary means, such as physical examinations, blood pressure, determinations and uranalysis. On the contrary, these clinical manifestations of nephritis may be obvious while the phthalein test is still quite normal.

Salt retention.—As stated above, salt retention is a valuable diagnostic hint in the impairment of renal elimination. Mosenthal (6) in an exhaustive article states that in nephritis, two distinct types of excretion are found.

a. Salt retention not associated with deficient nitrogen elimination.

b. In advanced cases of primary or secondary contracted kidney characterized by hypertension and terminations in uremia, the quantities of salt and nitrogen are both diminished.

In no instance has the combination of nitrogen retention with sufficient salt excretion been met with.

It has been found by Frothingham (7) and others (8) that one of the most useful early signs of impaired renal function, is the delay in the elimination of chlorides in the urine.

In summarizing the data as enumerated above, one must draw the following conclusions:

1. Dye substances by themselves are not always absolutely dependable in the determination of renal eliminative power.

2. Accurate data can only be obtained by the use of a series of function tests.

3. The constancy of salt retention in the functionally impaired kidney.

In view of these facts I deemed it advisable to find a salt which could be administered intravenously, one that could be eliminated rapidly by the normal kidney and detected by a reagent. Sodium salicylate appears to comply with these requirements. This drug when used intravenously makes its appearance in the urine from within two and a half to five minutes. Its presence can be recognized at once by the appearance of a fine violet or purple color when collected into a test tube containing three c.c. of a one per cent. solution of ferric chloride.

Previous use.—This drug was used intravenously by many authorities, in the treatment of rheumatic fever. Thus Mendel (9), Reubens (10), Winkelmann (11) and in this country, Lewis A. Conner (12) have advocated its use intravenously for the treatment of the various forms of rheumatic fever with varying results. This made it unnecessary for us to test its toxicity on animals prior to our use for our present purpose.

These authors used the drug in doses even as high as thirty gr. without any ill effect, but we found that for our purpose one gram is sufficient. This is dissolved in five c.c. sterile distilled water, or, one can also use any of the ampules that are put up by many drug concerns who specialize in intravenous products.

In the early stages of our experiments we prepared the solution ourselves, but later we resorted to the

*Read before the Urological Section, New York Academy of Medicine, May 20, 1925.

use of ampules containing one gram of sodium salicylate dissolved in five c.c. of an isotonic solution.

Technic.—Half hour before the test, the patient is ordered to drink about two tumblers of water, to insure good urinary secretion. The patient is then cystoscoped and the ureters catheterized. After a sufficient amount of urine is collected for laboratory tests, the sodium salicylate is injected intravenously and exact time noted. Two test tubes are prepared, each containing three c.c. of a one per cent. solution of ferric chloride. After exactly three minutes have elapsed from the time the injection was made, the urine is now collected into the two test tubes. In a normal kidney, a fine violet color immediately appears, rapidly increasing in intensity. The reason for waiting exactly three minutes is that often, when the urine is concentrated due to lack of water ingestion and when strongly alkaline a flocculent precipitate may take place with the reagent of the ferris chloride. By not collecting the urine before three minutes have elapsed, this can be avoided.

While our experience with this test in nonsurgical renal conditions is as yet limited, we are convinced that in surgical conditions it is of undoubted value. We shall quote from our records a few cases to illustrate the value of its use. Its importance lies in the fact that in a normal kidney the drug makes its appearance from within two and one half to five minutes, most often three minutes. Any delay after five minutes usually indicates impaired or interfered renal function, and the longer the delay the greater is the impairment or interference. The drug is easily detected in mixed urine (from several patients) in dilutions of one to ten thousand. For the sake of brevity, only the salient points will be enumerated.

Case I.—U. C., boy of nineteen, complained for past year of frequency of urination, urgency, occasional hematuria. Both ureters were catheterized. Left side almost clear urine. Right side showed a pale cloudy specimen. Microscopically the right side shows much pus, and many tubercle bacilli. Sodium salicylate given intravenously showed up strongly on the left side within four minutes, and only the faintest possible trace on the right side after a lapse of fifteen minutes. Nephrectomy at the Bronx Hospital revealed caseous destruction of almost entire parenchyma with a thin border of cortex left.

Case II.—A. R., Bronx Hospital (11851), a female patient convalescing from a double pyelitis; sodium salicylate showed up in three minutes on both sides.

Case III.—J. F., male, aged fifty-three, Bronx Hospital, nephrectomy previously performed on right side for calculous pyonephrosis. Left side showed up the sodium salicylate in three minutes. The remaining kidney had been previously established as functioning normally.

Case IV.—Bronx Hospital (2897), a woman whose kidneys have been previously established as negative, the sodium salicylate appeared in three minutes.

Case V.—Mrs. P., aged forty-nine. History of renal colic and backache extending over a period of three years. X ray revealed two large stones and two smaller ones in her right kidney. Catheterization revealed clear urine from left side and thin pus from the right side. Sodium salicylate intravenously showed up in three minutes on the left side and practically none from the right side in fifteen minutes. Nephrectomy at the Bronx Hospital revealed several large stones, abscess formation and complete destruction of the kidney substance by sacculated abscesses.

Case VI.—A. R., male (Bronx Hospital, 11731), suspected renal calculus, but x ray was negative, urine negative. Sodium salicylate came down on both sides in three minutes. No obstruction found.

Case VII.—H. K. (Bronx Hospital, 11935). Admitted for renal colic. Sodium salicylate appeared on right side in three minutes, and on the left side in fourteen minutes. X ray revealed a stone on the right side, at the ureterorenal junction. Pyelogram showed a moderately dilated pelvis. The impaired elimination was no doubt due to the back pressure caused by the nonescaping accumulating urine in the renal pelvis.

Case VIII.—N. P. (office). Young adult male with a persistent phosphaturia, causing an irritable bladder. Ureteral catheterized specimens were negative, and sodium salicylate showed up on both sides in three minutes.

Case IX.—Female patient at the Beth Israel Hospital (O. P. D. 347). Laboratory reported a negative urine. Patient complained of backache. Sodium salicylate appeared in three minutes on both sides.

Case X.—Mrs. G. (Bronx Hospital 9734), a case of chronic cholecystitis and chronic appendicitis. Urine negative. Sodium salicylate appeared within four minutes.

Many other cases in which sodium salicylate was used gave similar results as described above, and it would be futile to enumerate any others.

It appears that when elimination on one side is impaired, the remaining side, if not diseased, excretes the salt faster and in larger amount than a kidney whose mate is carrying one half of the burden. Sodium salicylate cannot be given intramuscularly, because it leaves painful indurations and its elimination is not as accurate. On the other hand, its detection is not hampered by the occasional traumatic hematuria which arises from instrumentation. This salt has great possibilties, also in medical nephritic conditions (without ureteral catheterization) if properly worked out.

Thus, the time is to be determined as to how long it takes for its complete excretion from the normal kidneys and then compared with that of impaired kidneys and thus develop a working table. This may be stated in the following manner:

The patient is ordered to consume about 150 to 200 c.c. of water half hour prior to the commencement of the test. Five minutes before the drug is given intravenously the patient empties his bladder. Five minutes after the drug is administered, the patient urinates into a receptacle and the urine is tested with the reagent. If elimination is normal, the drug will now make its first appearance. From now on, the urine is tested every hour, providing it made its first appearance, and finally noting when it is no longer detected. In hospital ambulatory cases, the patient can be instructed to carry out the test himself and produce the final data for interpretation.

CONCLUSIONS

1. No dye substance by itself is absolutely reliable as a renal function test.
2. Accurate data can only be procured by using a combination of several tests.
3. Retardation of salt elimination is fairly constant in renal impairment.
4. Sodium salicylate is quickly eliminated by the normal kidney and held back by the diseased one.
5. The presence of sodium salicylate can be detected in the urine as quickly as any dye substance.
6. In surgical conditions of the kidney, sodium salicylate is an aid in determination of renal function.
7. Sodium salicylate is also a mild urinary antiseptic.

Regional Anesthesia in Urological Surgery*

WINFIELD SCOTT PUGH, M.D.
New York

On visiting the large surgical clinics of Europe one cannot help but be impressed by the great strides they have taken in the art of local and regional anesthesia. In some institutions local has almost entirely supplanted general anesthesia. At other clinics its use has not extended quite this far, but it is everywhere notably on the increase. It is most interesting to see an all local anesthesia clinic as is often found in the services of Illyes, Braun, Kappis, Willms, Narath, Denk and others. In urological surgery its importance is especially emphasized by Illyes, who rarely employs general anesthesia.

Local anesthesia becomes of especial importance to those of us who are doing urological surgery. This because of the untoward influences which general anesthetics have on the whole or parts of the urinary mechanism which is often already extensively diseased.

The baneful effects of general anesthesia are particularly well emphasized in those suffering from prostatic hypertrophy, associated with all the evidences of chronic urinary obstruction. In these cases the renal function is at a low ebb, the blood urea is comparatively high, while an examination of the urine often shows considerable albumin, pus and casts. Back pressure often gives rise to a chronic nephritis and pyelonephritis. Associated with these conditions but beyond the urinary tract are usually the evidences of the cardiorenal syndrome as manifested by emphysema, arteriosclerosis, hypertension and myocarditis. Aside from this we must also remember that the advanced age of these patients greatly diminish their reserve force.

It has been our custom during the past few years to carry out most of our urological operative procedures under local or regional anesthesia. In considering this subject we will divide these procedures into three main groups as follows: First, kidney and ureter operations; second, bladder, prostate and urethra; third, the testes, their coverings and the spermatic cord.

In the first group we use paravertebral anesthesia. In the second group the sacral anesthesia and in third division the usual hernia anesthetic technic are employed.

ANESTHETIC SOLUTIONS

In practically every case we use straight neocaine one per cent. freshly made in distilled water. We have been unable to confirm the rapid diffusion of the solution with increased anesthesia by the addition of sodium bicarbonate. The use of this salt was originally recommended by Läwen and since strongly endorsed by Scholl, Meeker and others. We are of the opinion that the addition of suprarenal products not only does not improve our anesthetic media, but decidedly increases its toxicity. This viewpoint is also in accord with the researches of Lowsley (7), the report of Mayer (8) and the investigations of Schmidt (9). Neocaine in our experience is decidedly the best of the local anesthetics and properly administered is practically devoid of danger.

PARAVERTEBRAL ANESTHESIA

In carrying out the technic of paravertebral anesthesia, it is our custom to precede the actual injections of neocaine by the use of a nerve sedative. For this purpose we employ morphine sulphate 1/6 gr. and scopolamine 1/150 gr., given hypodermically about one hour before the operation. In our previous papers (10) we have called attention to the psychic factors involved and the methods employed to allay any condition of nervous excitation.

When ready to proceed with the anesthetic we

*From the Urological Department (James Buchanan Brady Foundation) of the New York Hospital.

place the patient on the edge of the operating table. His hands and forearms are placed between his legs, while the body is well bent forward, so that the vertebra will be made prominent. We have obtained the best results by combining a paravertebral injection in which we inject the eighth to the twelfth dorsal nerves, with a large regional block of the lumbar and lateral abdominal areas.

LANDMARKS

For the paravertebral injection proper, the angle of the scapula, the lower border of the twelfth rib and the spinous processes of the eighth to the twelfth dorsal vertebra are used.

For the regional block, the anterior and posterior superior iliac spines below, and the spinous process of the first lumbar vertebra and the anterior end of the eleventh rib above, are utilized as landmarks.

TECHNIC OF ADMINISTRATION

Starting at the lower border of the twelfth rib about four centimetres or roughly two or two and a half fingers' breadth from the spinous process of the vertebra we make a skin puncture. From this point we make a continuous series of wheals in the corium extending up to a point lateral of the angle of the scapula, which usually is opposite the eighth dorsal vertebra. In making these injections, the outfits of Labat, Babcock or Dunn are of assistance, but not indispensable. Pneumatic injectors of the type recommended by Farr are of distinct assistance, but occasionally fail when needed most.

Upon the completion of the series of dermal wheals mentioned we proceed to our paravertebral injections. The needle is passed through the wheal to the lower border of the eighth rib, injecting a little neocaine as we go. When the subcostal line is reached (which sometimes requires a little angling), the needle is slightly withdrawn and turned almost parallel to the rib, point headed toward the spine. The needle is then slowly passed along the lower rib border till we impinge on the transverse process of one of the adjoining vertebra, constantly injecting as we proceed. When the process is reached the point of the needle is turned slightly forward and fanwise injections of about five c.c. made at this point. This will block not only the intercostal nerves, but the very important rami communicantes as well. If we are successful in this, we should have not only a good anesthesia of the skin, but visceral anesthesia with relaxations of the abdominal wall.

In approaching the foramen between the transverse processes care must be taken not to use too much pressure on the syringe, as it is at this point that toxic symptoms usually appear. The same procedure is repeated with all of the intercostal nerves down to the twelfth. In the area of the twelfth dorsal nerve, it is advisable to spread the neocaine rather widely, as this nerve and its branches often diverge extensively in their course.

Upon completion of the paravertebral injections proper we proceed to the loin infiltrations or as it is sometimes called, the quadratus block. A wheal is raised about two and one half cm. from the spinous process of the first lumbar vertebra. Another is made close to the anterior end of the eleventh rib. Wheals are also raised just above the anterior and posterior superior spines of the ilium. From these four points superficial and deep injections are made toward the centre and toward each wheal. An injection made down through the muscular tissues at a midpoint on the crest of the ilium, and a midpoint between this and the twelfth rib in the posterior axillary line, will aid in the anesthesia of the perirenal tissues. In the loin, injection of about sixty to eighty c.c. of one per cent. neocaine are used; the total amount usually being about one hundred c.c.

Fig. 1.—Points of injection for paravertebral anesthesia.

The lumbar injections take good care of the ilioinguinal and iliohypogastric nerves as well as any other nerve branches that may stray into the field from above or below.

THE SACRAL ANESTHESIAS

Much confusion exists regarding the nomenclature of the various sacral anesthesias. The anterior sacral injections are called by Braun, parasacral anesthesia; by others it is called presacral and this latter appeals to us as more nearly correct.

Injection of the posterior sacral foramen is called by the French transacral, by Lowsley and others it is called parasacral. As the same process in the cervical, dorsal and lumbar region is called paravertebral, the reason for designating this procedure parasacral is obvious. Parasacral in this paper therefore refers to postsacral injections.

Sacral anesthesia proper seems to be pretty well fixed in our minds in spite of several attempts to misbrand it. Sacral anesthesia is of considerable value in cystoscopy, cystotomy, prostatomy and operations on the urethra, particularly in stricture. Sacral anesthesia alone is often etirely efficient for the performance of perineal prostatectomy. In simple cystotomy via the perineum we always employ sacral anesthesia. For suprapubic cystotomy, local infiltration of the line of incision combined with sacral anesthesia permits great freedom for operative manipulations within the bladder. Our technic simply consists in making an anesthetic wheal midway between the sacral cornua. We then plunge our long anesthetic needle through this at right angles to the skin and carry it down through the hiatal membrane until we strike bone; the needle is then slightly withdrawn and its point directed up the sacral canal.

The chief dangers here are puncturing a vessel or the dura; both of which are remote. When they do happen the needle should simply be withdrawn and reinserted. We should be rather careful to inject our anesthetic solution slowly; we have less ill effects by so doing.

PARASACRAL (POSTERIOR SACRAL)

For the performance of perineal prostatectomy we believe this method an excellent procedure.

After considerable experience we think the injection through the hiatal membrane (sacral anesthesia) combined with the injection of the posterior sacral

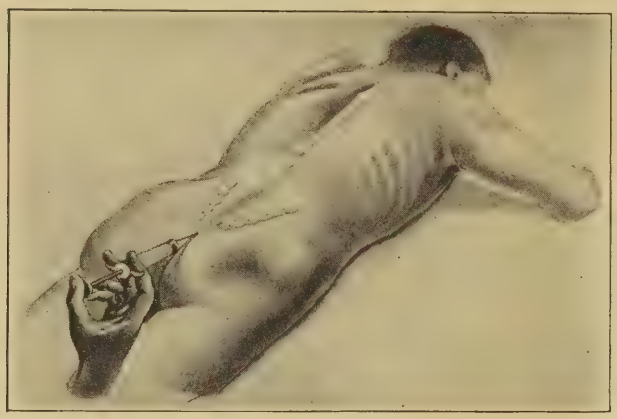

Fig. 2.—Sacral and posterior sacral anesthesia.

foramen to be the method par excellence for perineal extirpation of the prostate.

METHOD OF INJECTION

After making the usual caudal injections we locate the posterior sacral foramen by drawing a line upward and outwards from each sacral cornua to the posterior superior spine of the ilium. This forms a V. By making a puncture just below and slightly external to the sacral cornua we locate the fifth sacral nerve. This is done on each side. Following this, four small wheals should be made on the line from the cornua to the postsuperior iliac spine. Each one of these will be about opposite the spinous process of the sacrum, or roughly about a finger's breadth apart. Our needle is now passed directly into each one of these foramen and about five c.c. of one per cent. neocaine injected. Most of us have usually felt that these foramen run directly downward. Considerable observation has shown us that the third foramen alone runs in that direction, all of the others running downward and outward. It is by no means always possible to land in the foramen at the first plunge. Instead of that we usually strike the bone with our needle and after a few taps are in the canal. This method of injecting the posterior sacral foramen was first introduced by Danis in 1913. Braun in commenting on it states that it will never compete with his parasacral method. The method of Danis is, however, by far the better technic, and possesses less elements of danger. Puncture of both the rectum and bladder are possibilities of the Danis technic, but are extremely rare. Are not these multiple sacral punctures very painful? The answer is no; provided your original hiatal injection is a success. This fact is advanced by some who claim sacral anesthesia alone is sufficient for all conditions for which the injection of the postsacral nerves is recommended. Practical experience has demonstrated to us, however, that this is not quite correct.

Sacral anesthesia has been recommended by some for the performance of operations on the scrotum and testicles. It rarely works, however, and a little review of the nervous system of this region will give us the answer. It is true that it is an aid, but infiltration anesthesia is always required in addition.

SCROTUM AND TESTICLES

Practically every operation on the scrotum and testicles may be accomplished by the use of a block anesthesia extending entirely around the penis and scrotum at the point where they connect with the skin of the abdomen and thigh. In individual operations some slight additional anesthesia is at times a necessity. Illyes, Braun, Narath and others have recommended that four cardinal punctures be made, one over each spermatic cord as it works its way over the pubes and one more on each side at a midpoint of the junction of scrotal and femoral integument. From these points a complete line of injection passes through the subcutaneous tissues about the entire scrotum. Operations upon the scrotum itself such as ablation are readily accomplished by this technic alone. Where we wish to do an operation on the testicles or cord, the cord itself must be picked up at the opening in the internal oblique and injected with a few c.c. of one per cent. neocaine. If a good injection around the cord is made fanwise it will usually accomplish the same purpose. Operations upon the cord may also be readily performed by the use of the hernia technic. This is a satisfactory method and keeps the anesthesia and the operative field quite well separated. The fact that most of the operations on the testicle, epididymis and cord are now done in the inguinal region renders anesthesia of this area of great import.

INJECTION TECHNIC

In the area of the inguinal canal we are concerned chiefly with two important nerves: The iliohypogastric and the ilioinguinal branches of the first lumbar trunk. With the exception of the lumbo inguinal nerve from the genitocrural, all others are branches of the first lumbar terminals. Any operation on the cord, such as varicocele, hydrocele of the cord, or adenectomy of the inguinal glands, may be performed by blocking the important nerves mentioned above.

Fig. 3.—Points for nerve blocks of scrotum and testes.

A number of rather complicated methods have been suggested for this area, none of which are necessary. We really think that many surgeons have been prejudiced against local anesthesia, by the injection methods of the originators of hernia technic.

Operators are divided in their opinions regarding skin wheals in these procedures; some use two and others use three. As a matter of fact it really depends on whether one is accustomed to the use of

a very long or medium length needle. The extremely long needles are more difficult to control and we prefer the medium type. Three wheals are made in our technic: The first about two fingers above and internal to the anterior superior spine of the ilium; the second at the pubes just over the cord. The third wheal is placed midway between the first and second and just below Poupart's ligament. From point one superficial and deep injections are made fanwise into the structures in the direction of the anterior superior iliac spine. The needle is usually first introduced in a vertical direction and the injections made straight down into the deeper layers, injecting as we go. The needle is then withdrawn and attempts made to infiltrate the layers of muscles in a fanwise direction toward the crest of the ilium. In order to accomplish this the position of the needle must be increasingly oblique and the tip of the needle should finally reach the crest of the ilium through each layer. Following this we perforate the external oblique aponeurosis and inject toward the external anterior superior iliac spine fanwise. From wheal number two we inject directly down into the pubes also in a fanwise direction. We then inject under the abdominal aponeurosis and into the inguinal canal. In some cases we actually inject the cord itself. From wheal number three we make fanwise injections towards wheals numbers one and two. From this point we also complete the anesthesia by injections subcutaneously and into the fascia, the fluid being diffused widely. It is general experience that it is usually necessary to inject about twenty-five to thirty c.c. of a one per cent. novocain solution in each punctured area to achieve a satisfactory result.

SUMMARY

1. Local or regional anesthesia is practicable in all parts of the urinary tract.
2. It is an absolute necessity in cases of reduced functional activity or urinary obstruction.
3. Its use requires considerable coöperation on the part of the patient and for this reason it is not well adapted to the nervous type or in children.
4. With careful administration there is practically no postoperative shock or signs of toxemia.
5. Last but by no means the least important is the fact that it lowers the postoperative mortality greatly indeed.

229 West 101st Street.

Strangulated Inguinal Hernia of the Urinary Bladder*

Report of Two Cases

CYRUS F. HORINE, M.D.
Baltimore, Md.

Case I.—J. V., admitted to the University Hospital May, 1921, aged fifty-four years, history of hernia all his life, strangulation about six hours. An immediate operation under general anesthesia, modified Halsted hernioplasty was performed. About three inches of ileum (dark in color yet viable) and entire bladder was found in the sac. The right inguinal hernia was cured after two years.

Case II.—J. P., admitted to the University Hospital September, 1921, aged fifty-two years, with history of hernia since childhood, strangulation about ten hours. Two distinct masses could be palpated, one in the scrotum and the other just beyond the external ring. A Ferguson operation was done. Almost the entire bladder was found in the scrotum. A diverticulum of the sigmoid was found adherent to the peritoneum which was pulled down through the external ring. This was resected, using a purse string suture to close the opening. The patient was discharged from the hospital on the twentieth day as cured but there developed a recurrence in six months. He has so far refused a second operation.

In these cases the hernia were strangulated in the sense that they were not reducible. The blood supply was not entirely strangulated. Hernia of the bladder is found rather frequently, some authors stating it to be found in one per cent. of all cases of hernia. In many of the inguinal hernias the bladder may be found protruding into the canal. Strangulation of the bladder is seldom seen. Because of the rarity and the possibilities of injury to the bladder in doing herniotomy I am reporting these two cases. Both cases were proved cases of bladder hernia by dissecting away the parietal peritoneum and tracing the ureter into the mass.

Watson in his recent work on hernia gives a detailed study of bladder hernia. He collected 406 cases of bladder hernia up to 1923. He finds it to occur twice as frequently in men as in women. This is probably due to the occurrence of bladder hernia so frequently in the inguinal canal and because inguinal hernia is more common in men than in women. His statistics show bladder hernia to occur in the inguinal canal in 280 cases, in the femoral canal seventy-nine cases. Other varieties were two of the perineal type, one obturator and five ventral. Of the cases of bladder hernia he reports fifty-nine of them to have been of the strangulated variety. Of these twenty-nine were paraperitoneal, eleven extraperitoneal and five intraperitoneal. In fourteen cases the variety was not given. The two cases reported above were of the extraperitoneal variety.

The mortality in the fifty-nine cases was about twenty per cent. This type of hernia may easily be overlooked and the bladder wall may be injured or mistaken for a thickened peritoneal sac, consequently serious complications with a more grave prognosis. Eggenberger found a mortality of forty per cent. where bladder injury was not recognized until after operation.

*From the Department of Surgery, University of Maryland.

The Value of Uranalysis in a General Examination Compared with the Blood Chemistry

WALTER A. COWELL, M.D.
Olean, N. Y.

So much is constantly appearing in our medical journals upon every conceivable subject pertaining to medicine and surgery that one really should feel that one has a justification and a real message to impart when one takes up the pen to make a further contribution. Yet what I shall report in this brief article will not be new to many of the profession. The only purpose is to stimulate a great many more of our members to better, more accurate and exact work. This cannot be done by reading such an article as I am now writing, but by beginning to follow some of the methods suggested, and so to realize the great help and real pleasure that will come from a realization of the information gained in the individual case and the better conception of disease processes which from time to time will come under personal study. Great personal injustices are often done to patients because of an absence of study which is within the ability of every practitioner of medicine with the expenditure of but little time, and the reward is large in satisfaction to both patient and medical advisor when the effort is made. I will attempt to prove my hypothesis by adducing such points only from my case histories which bear directly upon the subject under discussion, and will not give the full histories in the cases cited.

Case I.—Mr. R. P., aged thirty, applied to a medical examiner for an examination for life insurance in May, 1924. Prior to his application he had been feeling fit and was in excellent health as far as he knew. Upon being examined, a trace of sugar was found in the urine. Nothing else was found which would prevent his acceptance by any insurance company. He was advised to go home and for one week abstain from candy and sugar and then to report for a second uranalysis. Since this showed a trace of sugar, he was advised that he had diabetes mellitus and was immediately placed upon a restricted diet. Beginning at this time he gradually began to lose weight and energy, and found it hard to perform his work. To add to his difficulties his only child, a son, became ill with pulmonary tuberculosis and was taken to a county hospital, the parents bravely undertaking to do a considerable share in his maintenance at a real sacrifice. The mother wished to go out to work but felt that she could not do so because of the oversight of her husband's dietory régime. The physician who examined the child was told of the father's supposed condition, examined the urine, confirmed the diagnosis and advised him to follow the diet as previously prescribed.

This patient called upon me on September 25, 1924, giving the history as outlined. The uranalysis showed a small quantity of sugar by Benedict's solution. A blood sugar examination, made upon the following morning after a fourteen hours' fast, showed a blood sugar content of .095 per cent. (normal .06-.12 per cent). Our patient was now advised to disregard the diet which he had been following, and to go upon a full general diet including sugar, candy, honey, bread, pie and cake, together with anything else that he might wish. At the end of another week, after a fourteen hour fast, the blood sugar examination showed a content of .0975 per cent. Here was clearly a case of renal diabetes, for which no concern need be felt. The wife has since gone to work, the father has been eating generally, and has gained in weight and efficiency. The family has regained its hope and happiness.

Case II.—Mr. L. S., called upon November 15, 1924, having been sent by the patient in Case I. This man had been examined for insurance and a trace of sugar had been found. He was advised to go for two weeks without candy or sugar, and again report. At the close of the two week period a slight reduction was present in Benedict's solution. A blood sugar estimation following a fourteen hours' fast showed .12 per cent. sugar, much to the relief of the patient. This, like the first, was a case with a low slop over point of the kidney.

Various skin conditions may have their bases in hyperglycemia with a sugar free urine. In proof of this statement I submit the following three cases:

Case III.—Mr. C. H. had had a recurring furunculosis. His physician had made repeated examinations of the urine for sugar without success. A blood sugar estimation showed .17 per cent. sugar to be present. Under diet with the Allen treatment all traces of cutaneous disturbance passed away and the blood sugar concentration fell to .10 per cent.

Case IV.—December 22, 1924, a man, J. Z., came to me. He was a sight to behold! His ears were covered with eczematous scabs, his face was covered with a dry eruption of eczema, both hands were raw upon the backs and the eruption of a dry type covered the arms. The itching was intense and very painful upon the raw places of the hands when the perspiration ran into them. He had seen seven other physicians within the past four weeks, with no benefit, and as a result was quite discouraged. The urinary analysis showed no albumin present, no sugar, no indican, and microscopically the urine was normal. His blood chemistry showed his urea nitrogen to be 20 mg., creatinine 1.5 mg. and sugar .17 per cent. His hemoglobin was 100 per cent. and Wassermann negative. The diagnosis was made of an eczema based upon a hyperglycemia. He was next seen five days after his carbohydrate intake had been restricted. All moist patches upon the hands had cleared up and healed over, the itching was much less and sleep was now possible. He was seen again December 31, 1924, and the appearance is much better than previously. The blood sugar today is .10 per cent.

Case V.—Dr. G. M. called upon me about three years ago with the request that I examine a sample of urine for sugar. This I gladly did and found none. Then he informed me that it was thus always

—that he had had it examined or had examined it himself in all about nine times, and no sugar had ever been found, but nevertheless, that he had suspected that there might be some diabetic trouble. I suggested a blood sugar examination and this showed a hyperglycemia of .17 per cent. He restricted his carbohydrate intake and reported in two weeks. The blood sugar content was now .14 per cent. but a troublesome low grade eczema which had been troubling him for some time had disappeared within the two weeks. This patient afterwards went to the Battle Creek Sanitarium to have his carbohydrate tolerance established, where the diagnosis of diabetes mellitus was confirmed. He has since had gangrene of the thumb.

Case VI.—July 4, 1921, R. C., aged fifty-three, usual weight 175 pounds, present weight 156, complained that for the past year he had been gradually losing weight and was constantly tired and indisposed to work. No complaint of craving for sweets, polyuria or polydipsia, was made. His uranalysis showed no albumin, no sugar, no indican, and nothing abnormal under the microscope. His functional phenolphthalein test gave 68 per cent. in 2′ 10″. His blood gave a negative Wassermann, and the chemistry gave urea nitrogen 28 mg., creatinine 2.2 mg., and the blood sugar was .175 per cent. The diagnosis was mild masked diabetes mellitus, masked nephritis, together with a general toxemia. This patient reported in a short time that he was feeling a great deal better and had gained considerably in weight under a restricted carbohydrate diet. In glancing over these cases the fact stands out that the blood sugar content has been about .17 per cent. in all. Possibly had the blood sugar been more, the urinary sugar would have soon appeared since .17 per cent. is the average threshold point, or in other words it is the concentration attained in the blood before the sugar begins to be excreted by the kidney, and glycosuria to appear. In Cases I and II we have kidneys with slop over points lower than the average, and hence our renal diabetes.

Aside from the diagnosis of masked diabetes mellitus, for the estimation of the improvement of our patients from time to time, the examination of the blood sugar offers an avenue of information which is superior to all other methods and in comparison to which the uranalysis holds a secondary place, sometimes giving us no data, when there is no glycosuria.

The blood chemistry holds a superior position when compared to the urinalysis in the diagnosis of the nephritides, the functional activity of the kidneys and in the prognosis of our cases. An interesting case has recently been under my observation from which we may make the deduction that we may have a frank nephritis but with little impairment of the functions of the organs as shown by the chemistry of the blood.

Case VII.—Mrs. E. M. S., aged thirty-eight, weight, present 128, normal 128; white, American, with one living child—no miscarriages. This patient called because of a troublesome urticaria. Her family history was negative except that one brother had died of diabetes mellitus. I will not go into the case extensively except to draw upon the points which I wish to emphasize. In addition to the urticaria, dermographia was present. The uranalysis showed albumin to be present in a marked amount. No sugar, indican was very heavy and under the microscope numerous hyaline casts were found to be present. The Wassermann test was negative, the hemoglobin was 100 per cent. (Dare), and the chemistry of the blood showed urea nitrogen 17.6125 mg., creatinine 1.5 mg. and blood sugar .09 per cent.

The diagnosis was urticaria and kidney irritation due to an intestinal toxemia. The kidney condition is possibly the result of toxines which were simultaneously affecting the skin, but as yet the kidneys were not greatly impaired. Only by a chemistry of the blood could such a conclusion be made. This patient had taken excellent care of herself. Her teeth had been x rayed every three months for an extended period, and she has been under the care of several good physicians on the Pacific Coast before coming East.

Upon the other hand, we may find patients whose urine is normal but who have an impaired kidney condition as shown by the blood chemistry, and which I am pleased to call masked nephritis. This condition is much more prevalent than masked diabetes mellitus but as easily detected by the chemistry of the blood. I have the histories of a great many patients of this masked nephritic type, but I will select only one from this group which will illustrate the point very well.

Case VIII.—Mrs. A. E. S. called upon me on March 11, 1922, complaining of swelling of the lower limbs at bedtime daily. Examination showed that the heart was not enlarged—the sounds were normal, the pulse was 75, regular, of good tension, with a blood pressure of 145/75. Her functional kidney test gave 60.6 per cent. in 2′ 10″. Her uranalysis was as follows: Amount in twenty-four hours 3100 c c., no albumin, sugar or indican, microscopically negative. Her blood chemistry was as follows: uric acid 7.0 mg., urea nitrogen 23.35 mg., creatinine 2.56 mg., chlorides .53 per cent., and sugar .11 per cent. The diagnosis was masked nephritis, based upon the polyuria and the blood chemical findings which showed a retention of everything except the sugar content. This beautifully illustrates a condition frequently seen in which there is no acute irritation of the kidney as shown by an absence of albumin and casts, but a renal insufficiency due to a definite organic change in the organ as shown by the excessive creatinine content above normal.

The technic of making the examination for urea nitrogen, nonprotein, urea, creatinine, chlorides and sugar in the blood, can easily be mastered by any physician who cares to undertake the work. The modern textbooks will give sufficient information so that they may be worked out, and some of the analyses may be done in a few minutes. All that is necessary is a few chemicals and the proper glassware.

CONCLUSIONS

That the economic loss in some families from a mistaken diagnosis may be great as in Case I. That the examination of the urine alone, while many times giving valuable information, is at other times misleading, deceptive and bound to work injustice to many patients. That to wait for another physician to make the blood examination may be compromising. That all cases of skin affections should have

the blood chemistry examination—especially for blood sugar. That all general examinations are incomplete unless accompanied by a complete blood examination including its chemistry. That many cases of socalled diabetes insipidus may be cases of diabetes mellitus. That life insurance companies should follow up all cases of glycosuria with a blood chemistry both for their own sakes and in justice to their applicants. That the diagnosis, prognosis and course of some diseases, notably diabetes mellitus, nephritis and gout, are much more accurately gauged by the blood chemistry than by the uranalysis which, at times, is worse than useless by its misleading findings. That masked nephritis and masked diabetes mellitus can be diagnosed by blood chemistry. That the progress of the nephritic may be watched with the same satisfaction as that of the diabetic especially by watching the urea nitrogen. The creatinine findings are more indicative of structural changes in the kidney than of progress made by treatment.

The Diagnosis of Surgical Diseases of the Urinary Organs*

J. U. REAVES, M.D.
Mobile, Alabama

The cystourethroscopic examination of the urinary organs together with laboratory and x ray findings will enable us to diagnose early and accurately all of the socalled surgical diseases of the urinary tract. Notwithstanding this, however, most of these cases reach the stage where their lesions are advanced and much damage has been done requiring extensive surgical interference for their alleviation before the true condition is recognized. This is largely due to too much reliance being placed on internal urinary antiseptics, long continued bladder irrigations, or similar treatment. The procedure for making an early accurate diagnosis is time consuming, expensive, and it may be unpleasant, yet ineffectual treatment and invalidism are much more costly and disagreeable.

The need for careful urological diagnosis is proclaimed over and over again by that large army of patients who have been diagnosed and treated for some abdominal condition, operated and reoperated upon without relief, later to be found with the pathological condition in the urinary tract, also those who have their urinary chills interpreted as malaria and treated with quinine and trips to the mountains season after season. Over fifty per cent. of the patients with right sided renal and ureteral lesions diagnosed at the Mayo Clinic have had one or more futile abdominal operations performed. Ninety per cent. of the urinary calculi in my own practice have at some time since the history of the symptoms began which led to a diagnosis of stone been treated for malaria, and practically all of them have taken urinary antiseptics at one time or another to clear up their urine.

The physical examination is often negative in lesions of the genitourinary tract. However, a general examination to rule out tuberculosis, diseased heart, tumor metastases, and other conditions, is important. In the kidney region, tenderness and rigidity on palpation as well as tenderness on deep percussion are the chief signs looked for, remembering that the normal kidney is seldom palpated even in the thinnest abdomen. By abdominal, rectal and vaginal palpation, much can be learned about the bladder. The lower ends of the ureters are palpable in the female and I have had three cases where ureteral stones could be felt. In the male the prostate must be looked into and properly diagnosed as to the degree and character of enlargement and the obstruction to the urinary flow caused by the enlargement.

Each case presenting has a tentative diagnosis made by obtaining information of the present and past history, a complete physical examination, a complete urine examination, using one of the multiple glass tests, noting residual urine if present, bladder capacity and tone, the making of necessary smears and their microscopical examination, rectal palpation of prostate and seminal vesicles with a microscopical examination of their secretions, examination of urethra for possible stricture, then a systematic cystourethroscopic examination with x ray collaboration.

With the proper use of the x ray and cystourethroscope almost all urinary lesions can now be early and accurately diagnosed. Therefore fewer extensive surgical procedures are necessary and fewer malignant diseases are engrafted upon primarily benign lesions.

X rays are only indirect evidence, and their findings are gross and not microscopic; on the other hand cystourethroscopic procedure alone is only of value in locating lesions in the bladder and urethra, for collecting urine from each kidney for analysis, culture or functional test, or for instrumentation or topical treatment to locate pathology in the urinary tract. Therefore it is necessary to combine both röntgenographic and cystourethroscopic examinations as either alone is of relative little value.

When the preliminary röntgenogram is negative, all the cystourethroscopic data possible should be collected before further röntgenograms are made. Our routine technic for cystourethroscopic examination is as follows: 1. A thorough exploration of the bladder wall, remembering that most all bladder pathology is in the lower quadrant; 2, a study of the appearance of the sphincter muscle; 3, examination of the posterior urethra; 4, the ureteral orifices are inspected for size, shape, patulence and evidence of inflammation noting the efflux from each; 5, catheterizing each ureter, using lead catheters, determining the presence or absence of obstruction due to stone, stricture, tumor or kinking; 6, the collection of sufficient amount of urine for laboratory examination from each ureter; and 7, a differential functional test, for this I use phenolsulphonephthalein and find it extremely satisfactory.

From this point on the technic is entirely dependent

*Read before the Harrison-Stone County Medical Society, Gulfport, Miss., March 4, 1925.

on the individual case, and varies considerably. If pyelography is to be done, the appearance time of the phenolsulphonephthalein is carefully noted, if synchronous and within normal limits a small amount of urine is collected for a limited period. During this time the preliminary röntgenograms are made. If the usual difficulty of one catheter or the other refusing to flow cannot be overcome and there is evidence of complete inhibition of kidney function, no injection of pyelographic medium is made on that side. If this inhibition is due, however, to an obvious pathological condition, pyelography is done, your own judgment being the guiding factor.

Eighty-five per cent. of all stones will show in the röntgenogram without pyelographic solution in the pelvis of the kidney or ureter. Having lead catheters in the ureters facilitates greatly the reading of the röntgenogram in these cases. The fifteen per cent. of stones not visible in the film can often be discovered by passing a wax tipped catheter and noting the scratches thereon when the catheter is withdrawn. Even a large stone which does not cast a shadow in the röntgenogram will often show a thinning out of the pyelographic shadow at that point where the stone lies.

The appearance of stone presented with the cystourethroscope is striking and characteristic, and it is now conceded that no diagnosis of stone is accurate without cystoscopic confirmation, the reason being that direct visuality has less room for fallacy than any other method of diagnosis. The cystoscopist must be careful that his instrument does not run in under the stone or stones, the stones being large enough to be held up by the cystourethroscope are thus out of the field of vision. In cases where urinary obstruction is met with in the urinary outflow, thus bringing the detrusor muscles into increased action causing a diverticulum or diverticula and the stone lodges and enlarges within a diverticulum of the bladder wall, the cystourethroscope is of inestimable value in clearing up the diagnosis. Trabeculation of the bladder wall is also caused by incoordination of the detrusor muscles and the vesical sphincter, this being an early sign of cerebrospinal syphilis. It is marked on the anterior wall and may be accompanied by a relaxed spincture outlet.

Stricture of the ureter is best diagnosed by the röntgenogram, having the ureter distended with pyelographic solution, making the diagnosis of stricture when distortion of the ureter occurs in varying degree. This is quite a common condition in women and Morrissey finds stricture of the ureter frequently in the male and believes the condition to be due to focal infection.

In all but the most simple cases of hematuria you must use instruments of precision to make an accurate diagnosis. Sixty-four per cent. of Chute's cases were due to new growths in the urinary tract. Kretchmer claims that hematuria, with few exceptions, means the presence of organic disease in the urinary tract. The bleeding point may be in the posterior urethra or adnexa and draining back into the bladder; it may be from the bladder wall itself or some growth attached to the bladder wall; or it may be from above—the ureters and kidneys. In any case it is imperative that a cystourethroscopic examination be made while the hemorrhage is present, thus facilitating the ready location of the bleeding point. The diagnosis of idiopathic hematuria should never be made only after autopsy has failed to reveal the cause of the hemorrhage. True hemorrhage may be differentiated from hemoglobinuria by the use of the microscope.

Eight per cent. of all tumors of the body are found in the urinary tract. In almost all cases their first symptom is hematuria. This hemorrhage may be either initial, total or terminal, but comes on suddenly in the majority of cases. It may be either intermittent or constant, may continue for days, weeks, or months in spite of any or all palliative treatment; or may cease as abruptly as it began. Here the cystourethroscope will clear up the diagnosis at once, making an examination as soon after the hemorrhage is first noted as possible. To one experienced in interpreting pyelograms, diagnosis of small and early renal tumors can be made, and operative treatment instituted before metastasis has occurred. In tumors of the carcinomatous type operation and radium are the procedure as diathermy proves futile in these cases, serving only to delay until the patient is in such physical condition that operative measures cannot be undertaken.

The treatment of tumors of the bladder and posterior urethra other than those of the carcinomatous type is diathermy. This procedure can be carried on in any well equipped urological office. The only preparatory or aftertreatment required is some internal treatment to render the urine aseptic. The number of treatments vary according to the condition of the individual case at hand.

An early diagnosis and proper treatment of renal tuberculosis is of extreme importance. The characteristic symptoms are: age twenty to thirty, urinary frequency both diurnal and nocturnal, hematuria present in seventy-three per cent. of the cases, loss of weight, fever and pain as late symptoms. Renal tuberculosis is always secondary, therefore delay in making your diagnosis and removing the infected kidney usually results in a bilateral involvement.

In the posterior urethra the cystourethroscopic picture is for the most part reflecting true pathology lying beneath, be it prostatitis, vesiculitis, enlargement of the prostatic lateral lobes either into the bladder or posterior urethra, enlargement of the middle lobe of the prostate, or enlargement of the subcervical group of glands or glands of Albarran, or any combination of these. When the enlargement of the middle lobe of the prostate or the subcervical group of glands is the cause of the urinary disturbance, they can easily be fulgurated through the cystourethroscope, and in some cases complete relief of the patient's symptoms is obtainable, which will last for several years throughout the patient's life. Most patients have to be operated upon, but the cystourethroscope is the means of accurate diagnosis.

CONCLUSIONS

A brief paper such as this naturally is inadequate in covering the field of urological diagnosis. Its chief object is a plea for any early recognition of lesions of the urinary tract. The methods outlined are time consuming and expensive, but ineffectual treatment based on an incomplete diagnosis is far more costly and disagreeable. The importance of early and accurate diagnosis is apparent.

The Problem of Forcing Fluids for Infections of the Urinary Tract

CHARLES EVERETT HAINES, M.D.
New Rochelle, N. Y.

There are a number of pathological conditions wherein it seems imperative to force fluids in quantities out of all proportion to the patient's willingness, and in many cases ability, to imbibe them. Common among these are infections of the urinary tract in its several parts—pyelitis, ureteritis, cystitis, and urethritis.

While there are several methods of treating these infections, such as irrigations, instillations of bactericides, change in the reaction of the urine, cathartics, the drug hexamethylenamine, rest and diet including the usual prohibition of the condiments, the importance of large quantities of fluids cannot be overestimated.

Yet patients are either careless of the injunction to drink large quantities of water or they very soon tire of obeying it; besides, to many patients large quantities of water as interpreted by them are too meagre to be of any real use. Indeed, there is often a limit to the amount of fluid that even a skillful nurse can persuade the patient to drink, a limit often far below what seems a minimum for any therapeutical value. Add to these drawbacks the fact that whether a patient is willing or unwilling, water, in unusual quantities, becomes in time repulsive, and the problem of forcing fluids seems a grave one.

There are, of course, several methods of forcing fluids other than directly by mouth. These are even less satisfactory, however. There is the Murphy drip method, but this often fails because the fluid is partially expelled before it can be absorbed. There is hypodermoclysis which is rather cruel treatment and soon reaches its limits. There is the method of infusion which is not satisfactory because of the risk of injecting bacteria or air emboli into the bloodstream. And there is the method of directly flushing the lower urinary tract including the pelvis of the kidney through catheterization, but it is always resorted to with great hesitation for fear of traumatizing the mucous membrane; besides, considering the risk and the amount of work involved, rarely does enough water reach the urinary tract to make this method of treatment seem worth while. And so we are face to face with the problem of how to give patients suffering from infections of the urinary tract more fluids by mouth.

Ever since 1908, when Einhorn first used the duodenal tube for alimentation in the treatment of gastric ulcerations, its use has gradually been extended to many other pathological conditions, both surgical and medical, including the forcing of fluids in cases of thromboangitis obliterans.

Would it not seem wise further to extend the use of the duodenal tube for forcing fluids by mouth in cases of infections of the urinary tract? Would it not seem that the duodenal tube is an adjunct, in any therapeutics requiring large quantities of fluid, the value of which cannot be overestimated?

After the duodenal tube has been passed Ringer's solution or tap water can be given through it by means of a Murphy drip at the rate of forty to fifty drops a minute. The amount which the writer has seen given in cases of thromboangitis obliterans was, at first, about 300 c.c. three times a day. This was gradually increased in some cases to 1500 c.c. every three hours six times a day.

Contraindications to the larger amounts were vomiting and a diarrhea which could not be controlled by bismuth subnitrate or by diet. In either case the amount of fluid was then reduced. However, it was usually found that very large quantities of fluid could be given after a few days of treatment without untoward effects.

The greatest difficulty in the entire course of treatment comes in getting the duodenal tube in place. This difficulty is well worth while, however, considering the importance of the result.

Whereas a nurse is quite competent to administer the tube, it is often excellent policy on the part of the physician to do it, or at least to be at hand for the assurance his presence will give the patient.

The tube is best given by the Lyons method which is comparatively easy and quick. Lyons gives the tube in the morning on a fasting stomach rather than at night as is Einhorn's practice. It is swallowed to the 55 cm. mark, thus getting the bucket into the stomach. A small glass of water is then given, the patient is placed on the right side, the head lowered and the hips raised on pillows. The patient is now encouraged to make slow swallowing movements until the 75 cm. mark has been reached. It will usually be found that the tube is in place in the duodenum in from twenty to forty minutes. In order to find out whether this is so a small amount of fluid should be aspirated through the tube and tested with litmus paper. If the reaction is alkaline it is usually a sign that the bucket is in the duodenum, but an acid reaction usually signifies that the bucket has not yet passed the pylorus. If the bucket is not in the duodenum the patient should be kept on the right side until it is.

In all cases the amount of the fluid given each day and the length of the treatment should be regulated according to clinical symptoms.

While treatment by means of the duodenal tube may at first seem somewhat heroic, it should be remembered, in the first place, that this appears the only satisfactory method for the administration of fluids in large quantities. Besides, once the tube is *in situ,* it can be allowed to remain thus for days, or if it is removed there is rarely any difficulty in the taking or giving it again.

SUMMARY AND CONCLUSIONS

1. In cases of infection of the urinary tract, from the pelvis of the kidney through the urethra, fluids in large amounts are indicated, yet are usually difficult to give.

2. The duodenal tube, it seems, can be used to do away with this difficulty.

Practical Therapeutics

THE THERAPEUTIC RELATIONSHIP OF DIGITALIS AND STROPHANTHUS*

EDWARD E. CORNWALL, M.D., F.A.C.P.
Brooklyn, New York

(*Concluded from volume cxxi, page 754*)

PARTICULAR THERAPEUTIC USES OF DIGITALIS AND STROPHANTHIN

It has long been known that digitalis has an almost specific action in the treatment of heart failure associated with auricular fibrillation. In this condition the irregularity of the ventricular action is rectified with resultant great improvement in the circulation. Digitalis brings about this rectification of the heart's action apparently by reducing conductivity at the auriculoventricular bridge so as to block unnecessary and disturbing impulses which come to the ventricles, and perhaps also by breaking up a "circus rhythm." Also, by slowing the conduction time between the auricles and ventricles it favors filling of the left ventricle, which is of special advantage in mitral stenosis. In auricular flutter it may similarly improve the circulation by reducing conduction; it may first change the flutter into fibrillation.

Has digitalis any value in the treatment of heart failure occurring in conditions other than those associated with auricular fibrillation and flutter? Is the correction of an arrhythmia which functionally impedes the ventricular action its only beneficial effect? Thomas Lewis answers as follows: "The chief value of digitalis lies in its power to control the ventricular rate when fibrillation of the auricles has come. . . . A chief cause of the rapid heart action when heart failure threatens or has come, is fibrillation of the auricles, and it is in this condition that digitalis acts so beneficially; it reduces and holds the rate within normal bounds. The reduction of accelerated ventricular rate is the only important action of the drug of which we have knowledge. There are few if any instances of which we know with certainty, in which digitalis acts beneficially except cases of accelerated action; there are few cases of acceleration in which the drug produces unquestionable benefit apart from those provoked by fibrillation of the auricles. . . . Those who regard digitalis as a cardiac tonic mistake its character; its chief action is to slow the heart" (13). And James Mackenzie agrees with Lewis in the following words: "It is to be observed that such a reaction (slowing of the heart produced by digitalis) rarely occurs in conditions other than auricular flutter and fibrillation. . . . As a rule, digitalis has little or no effect on hearts with normal rhythm. So far it seems that the beneficial effects which result from digitalis are not due to any other cause than the mere slowing of the heart rate" (14).

The therapeutic indications of strophanthus are more extensive than those of digitalis, the limitation of the latter, as laid down above, being accepted. They include all conditions where heart failure is due to or complicated by intrinsic weakness of the heart muscle, that is, by diminished tonicity or contractile energy; and they parallel the digitalis indication to produce therapeutic heart block in auricular fibrillation and flutter. It may be that the power of strophanthus to depress conductivity is generally less than that of digitalis, but it acts better than digitalis in cases of auricular fibrillation with much loss of tonicity of the ventricles, as Vaquez pointed out.

In actual or threatened loss of tonicity from myocardial weakness occurring in the acute infections strophanthus is indicated. In pneumonia the author has used and recommended it as the preferred heart stimulant for many years (15). In these acute infections, where the blood pressure is usually low, strophanthus has the special advantage of not stimulating the vagus.

In chronic myocardial degeneration with heart failure strophanthus can be used to increase the strength of the cardiac contractions, the dose being graduated according to the needs of the case. When given in place of digitalis for a heart blocking effect in auricular fibrillation with much loss of tonicity, full doses may be required. In any case of pathological dilatation strophanthus is the most effective drug that we have.

Great care must be taken in giving strophanthus after a strong course of digitalis, as it can precipitate digitalis poisoning; but if given before a course of digitalis it is not likely to prove thus dangerous, being quickly eliminated or destroyed.

The teaching that digitalis is essentially a regulator of the heart's action, that is, of the rhythm and rate of the heart's action, while strophanthus is a direct heart stimulant, that is, a strengthener of myocardial contractions by direct and exclusive action on the heart muscle to increase tonicity and contractility, gives us an explanation of the difference in effect of these drugs which was observed clinically and throws light on their therapeutic relationships.

*Read before the American Therapeutic Society, Atlantic City, N. J., May 22, 1925.

ALPHA-LOBELIN IN THE TREATMENT OF ASPHYXIA NEONATORUM

August Oberbeck, M.D.
New York

On account of the many incidents during labor the newborn is not infrequently threatened with asphyxia which, unfortunately, does not always respond to the usually employed methods of treatment. In fact some of these result in actual damage to the patient. Rupture and displacement of the delicate organs have resulted from too vigorous manual methods and insufflation pneumonia is an embarrassing sequel.

The indirect stimulation of respiration, as a secondary result of the treatment administered, has in the past constituted the chief difficulty in meeting this condition satisfactorily. In view of these facts, the discovery of an agent acting specifically and promptly as a stimulant to the respiratory centre will doubtless arouse great interest in the medical profession and also mark a new epoch in scientific drug therapy.

Such an agent has been found in alpha-lobelin. Extensive laboratory and clinical experiments have demonstrated beyond doubt its value as a direct respiratory stimulant acting without influence upon other physiological functions.

The following are typical indications for and results obtained by the use of alpha-lobelin.

1. Maternal dystocia due to kyphotic pelvis; symphysiotomy and forceps delivery; marked asphyxia neonatorum livida; irritation of the throat showing reflexes absent; insufflation without effect. Within thirty seconds after the injection of one twentieth grain alpha-lobelin respiration was fully established and continued.

2. Fetal dystocia due to compound presentation (hand and head); hand pushed back and flexion of head restored; forceps delivery; asphyxia neonatorum pallida. Hypodermic injection of one twentieth grain alpha-lobelin resulted in superficial and arrhythmic respiration; one half the dose was therefore repeated ten minutes later. Result: normal breathing established and maintained. As the seriousness of the case suggested the additional use of a diffusible stimulant, whiskey was administered by hypodermic injections in the emergency.

3. Fetal dystocia: prolapse of cord. Asphyxia neonatorum livida responded promptly to a single injection of one twentieth grain alpha-lobelin. No further treatment was necessary.

I might also state that I had occasion to observe the vital effect of alpha-lobelin in two cases of veronal poisoning caused by overdoses. As the symptoms indicated full assimilation of the drug, lavage would have been useless and therefore was omitted. The patients were moderately cyanosed and respiration was very slow and superficial. Both received three intramuscular injections of one sixth grain alpha-lobelin in hourly intervals, and after a prolonged sleep (fourteen to sixteen hours respectively) they awoke without any apparent aftereffect of the veronal overdose.

Heliotherapy.—R. Plato Schwartz (*Boston Medical and Surgical Journal,* August 7, 1924) thus summarizes his opinions:

1. Thirty-three years have not produced universal confidence in the use of tuberculin in the treatment of any form of tuberculosis.

2. Heliotherapy has clinically proved the indications for its use on the basis of the general changes in the patient, the prevention of deformity, and the restoration of function in the affected joint, providing fundamental orthopedic requirements are met.

3. High altitudes have certain advantages but excellent results are being obtained at the seashore; at either level clean clear air is a necessity.

4. Systematic graduated exposure of the entire body, except the head, with careful observation of each patient as the period and extent of insulation is increased, seem to be of fundamental importance in any serious attempt at heliotherapy.

5. Clinical observations and laboratory investigations, at present, favor the opinion that the therapeutic value of the solar spectrum is not due to the effect of any one region; but is more the result of the combined effect of the entire spectrum.

6. Artificial sources of light are to be regarded with suspicion until it is proved that they reproduce the solar spectrum in extent and intensity.

7. The local lesion in the bone or joint should be completely immobilized during the acute stage, apparatus is indicated but should not interfere with insolation. Sinuses and ulcers should be unbandaged twelve hours each day and subsequent treatment should favor the restoration of function.

8. Surgery must be looked upon as occasionally essential in the conservative attitude toward treatment of osteoarticular tuberculosis, but to use it wisely requires a knowledge of when conservative measures have reached their full potentiality.

Spinacin, a New Protein from Spinach Leaves.—Albert Charles Chibnall (*Journal of Biological Chemistry,* September, 1924) describes the ether method by which a new protein, "spinacin," was prepared from the cytoplasm of spinach leaves. It was found to be insoluble in water and salt solution, but was soluble in a very small excess of either acid or alkali. It contained 16.25 per cent. N., and was free from CH.

Historical Medicine

Fifty Years in the Practice of Medicine*

E. E. MONTGOMERY, M.D., LL.D., F.A.C.S.
Philadelphia

The progress and development, during the last fifty years, in every department of business and science has been unexampled in any similar period of the world's history. The telephone, the application of electricity to transportation, lighting, heating, scientific and mechanical arts were then unknown.

Coal oil for lighting had but recently come into use. The employment of gasoline for promotion and propulsion was a consideration for the future. The wireless, the radio, radium, and the employment of the various forms of light were yet uncovered in the land of dreams.

When the physician contemplates the discoveries, now considered necessities, in other lines of human endeavor, he is constrained to ask himself, whether his own profession has kept apace with such steps of progress.

On the fifth of July, 1871, I entered the office of the leading surgeon of my native town, Newark, Ohio, to read medicine for a year, as was then the custom, preliminary to study in a medical college. I found but one medical book later than 1848, the year of my preceptor's graduation. As I had no ambition to qualify as an antiquarian, nor no desire then to lay a basis by which to determine the progress in medicine, I immediately invested in the latest textbooks. My acquisition of medical lore, outside that obtained from my books, was scant. I had an opportunity to hold a child undergoing the operation of tracheotomy, without anesthetic, for the removal of a grain of corn from the trachea. This operation was performed by the noted surgeon, W. D. Hamilton, of Columbus, Ohio.

The latter part of August, 1872, I came to Philadelphia to attend lectures. It was my first visit to a large city. I found it paved with cobblestones, its traffic was in horsedrawn cars and the boarding houses were neither palatial nor inviting. The water for drinking and bathing was pumped and supplied directly from the Schuylkill River, which was the drainage canal for the cities upstream, and as the cemeteries within the city limits lined the banks on either side it might be truly said that its citizens acknowledged the virtues of their living ancestors and drank those of the dead. Frequently upon drawing a bath, the indulger would debate whether he would be as clean after as before he had taken it.

The course of instruction in the medical college consisted of lectures given to the two classes in common. The second year a repetition in all but the chair of practice, whose occupant covered the subject in two years. The observing student of the second year knew just how each subject would be presented, even to the time for the introduction of the jokes. The only laboratory was the dissecting room, upon which neither prolonged nor systematic attendance was obligatory. Both the ambitious student and the one who dreaded the final examination depended largely upon extramural teaching for instruction. Among the teachers our oldest Fellow, W. W. Keen, was the most noted, and his Philadelphia School of Anatomy was highly appreciated and well patronized by the students of both Jefferson and the University. The former institution, which I attended, numbered in its faculty some of the most noted members of the profession. Its professor of anatomy, Joseph Pancoast, of whom student tradition said he could operate successfully for conditions where the patients were sure to die in the hands of others, would say to his classes, "Gentlemen, I can't tell you why it is, but when I wash a wound with a solution of bichloride of mercury, it heals by first intention."

The professor of surgery, then sixty-seven years old, commended laudable pus, decried the aspirator and discarded the Esmarch bandage. The most of the surgeons of that day prided themselves on their ability to operate without soiling their cuffs, and carefully washed their hands after, rather than before operating.

The professor of obstetrics was cleanly. He persistently urged careful washing of the hands before examination of the patient, but as the latter, and the introduction of the catheter, were to be done without exposure of the genitalia, the purpose of the cleanliness might be considered to have been defeated. In diseases of women, the examination of the genital tract was digital, without exposure, followed by the introduction of a tubular speculum around the external end of which the enveloping sheet was carefully drawn. The next step was the introduction of the sound, and if this instrument was not properly curved, he would bend it with his teeth. When expressions of disgust were made by the students, he would impress them with the necessity of having the instrument so clean that they need not hesitate to put it into their mouths. Today we would question its fitness for use after the physician had removed it from his mouth.

The chair of practice was newly occupied by Professor J. M. DaCosta, who began those marvellous clinics on diagnosis which made his name renowned and respected the world over.

The professor of materia medica, John Biddle, would be popular with many today, as he advocated alcohol as a specific in typhoid fever.

The candidate for graduation was expected to have spent three years in the study of medicine, the first year in the office of a preceptor and two courses of lectures, each six months in length. But one examination was required and that at the end of the second year in college. This examination was oral, and although the students were in a panic when the period for it had arrived, it was easy to pass and difficult to fail.

*Read before the College of Physicians, Philadelphia, April 1, 1925.

Some graduates, realizing their incompetence to trifle with life, sought hospital experience. Through the intervention of R. J. Levis I secured the position of official substitute (a new position) to the Philadelphia Hospital. An examination of the candidates for interns was required before a committee of the staff, but the report carried no weight against political pull. The nurses were more intelligent paupers, or more frequently less intelligent, who had political influence.

In spite of these handicaps, the institution afforded a wonderful field for observation. No glimmerings of aseptic or antiseptic measures had apparently yet reached the members of its staff, at least not enough to affect their practice.

It is true that Lister had practised antiseptic surgery with marvellous results. White in 1891 quotes Lister's experience in Glasgow in 1864-66, when under nonantiseptic methods his mortality was 45.7 per cent. and contrasts this with his work in Edinburgh, 1871-78, where in 553 grave cases, the mortality from septic diseases was but 0.36 per cent., while Spence in the same hospital who declined to practise antiseptic methods had a mortality from sepsis of 2.4 per cent., eight times that of Lister.

What opportunities were dawning for practitioners of surgery? Is it surprising, however, that American surgeons should have been slow in the adoption of methods which were discountenanced, and the results doubted, by the immediate confrères of their advocate? As usual, truth, sooner or later, prevails and the surgeons of the entire world were the gainers by the courage and persistence of one man. Every department of surgery was enriched and made safer by the practice of antisepsis and its subsequent simplification, in asepsis. Compound fractures, gunshot injuries, and hospital gangrene were no longer the dread of surgery.

It is interesting to observe how the same, or similar ideas impress workers in different parts of the world. Thus, in 1872 Battey in this country, Tait in England, and Hegar in Germany advocated the removal of the ovaries but each for a different reason. Battey to bring about cessation of menstruation when the function was attended with such pain as completely to incapacitate the individual for the enjoyment of life; Tait, where the tubes and ovaries were the seat of severe inflammatory and purulent conditions; and Hegar, to establish the menopause in severe hemorrhages occasioned by submucous myomata. Experience had disclosed that the occurrence of the menopause was not only followed by cessation of the uterine hemorrhage, but also by recession of the growths.

The greater safety afforded all operative procedures through the practice of asepsis led to an epidemic of surgery. Some questioned whether the future of the race was not imperilled through the frequency with which the ovaries were removed and a female surgeon advocated the removal of the male analogues where the possessor had specific disease, but this suggestion was not enthusiatically received.

Emmet added impetus to the wave of gynecic surgery in 1874, by his description of the operation he had devised for laceration of the cervix, called trachelorraphy, which he had been practising for twelve years and had, at that time, performed some two hundred times. He was heard to assert that had he supposed that it would be so frequently and unwisely performed he would have hesitated to make it known.

Appendectomy, truly an American operation, having been first performed by Willard Parker, of New York, in 1848, subsequently frequently performed by Morton, Keen, White and others, remained to our Fellow and confrère, John B. Deaver, to render fashionable and a source of revenue.

Regions of the body, which were considered outside the possibility of successful invasion, as the cerebral, spinal and chest, have become legitimate fields for investigation and treatment.

The removal of large ovarian tumors, denominated ovariotomy, is another American operation. It was first performed by McDowell, of Danville, Ky., in 1809, and after several operations by him fell into disuse until revived near the same time in 1844 by Atlee, of Pennsylvania; Dunlap, of Ohio, and Clay, of England.

Atlee bore an unprecedented onslaught of denouncement and criticism, but courageously and persistently continued his course, and lived to see ovariotomy accepted as a legitimate procedure the world over.

It has been estimated that Spencer Wells, of England, through the performance of this one procedure has added many thousands of years to the life of woman.

I had a practical application of the relation of sepsis to childbed fever, then known as puerperal fever. I had passed from the surgical service, where I had a number of cases of erysipelas, directly to the obstetrical wards, and my advent was followed by an outbreak of infection, called puerperal fever. I well remember the days and nights in attendance upon these victims and my sense of discouragement and depression when in April, 1875, three children were left motherless by the death of two women. Here, again, asepsis, the outgrowth of the tide which Lister had set in motion, led to the recognition of this disease as a result of infection and demonstrated the means by which it could be avoided. Then the hospital was the dread of the parturient woman, now it is her greatest safety.

From time immemorial, Cæsarean section had been recognized as an occasionally necessary method of delivery. In the early eighties, however, it was shown that a woman could be delivered by the horn of a cow with less mortality than by the knife of the average surgeon. The British obstetricians and their American followers resorted in all doubtful cases, where the dimensions of the pelvis would permit, to the destruction of the child by embryotomy. One general practitioner of Philadelphia laid claim to the credit of nineteen craniotomies.

I was so impressed with the need that the unborn child should have *its* chance for life, that I prepared and read a paper before the Philadelphia County Medical Society, February 14, 1883, on "Is Craniotomy Justifiable?" in which I asserted there were measures affording the child a chance for life which could be safely employed for the mother. Oettler, in 1870, had reported a woman living, who had undergone four deliveries by Cæsarean section between 1853 and 1863. Charles D. Meiggs, in refusing to

perform a third craniotomy for Mrs. Roelof, was instrumental in securing for her two children by successive Cæsarean sections, and she in her riper years had the comfort of seven grandchildren. The mortality was generally regarded as equalling thirty per cent. This was because the obstetrician of that day was influenced by the dictum "meddlesome midwifery is bad," and allowed his patient to exhaust her forces and become infected by repeated examinations and efforts at manual delivery, before the Cæsarean operation was employed. I insisted that the attendant should know in advance of the expected labor, the size and condition of his patient's pelvis, be prepared promptly to employ the proper means of delivery, avoiding the deleterious procedures and thus afford justice to mother and child. I closed the paper with the assertion, "The obstetrician should control events, not be controlled by them."

My suggestions were condemned by my contemporaries, but I have seen every proposition accepted as sound doctrine. As predicted the Cæsarean operation is employed with as much freedom and with greater certainty of success than was ovariotomy then. G. M. Boyd, a Fellow, reported in 1914 that he had performed forty-eight Cæsarean sections without a maternal death, and J. M. Martin, of Glasgow, in 1921 presented fifty-one. Thoms, of New Haven, Conn., reported a colored woman who had four Cæsarean deliveries between May, 1918, and November, 1921, in the last of which feeling that she had done her duty, the operator sterilized her.

The removal of the uterus for myomata and cancer marks another step in progress. These were operations infrequently performed fifty years ago and never for cancer. The cervix as a stump or pedicle was brought outside the abdominal wound, secured by a clamp, or transfixed by pins, and hemorrhage prevented by a rubber ligature below the latter. Baer, a Fellow of the college, ligated the uterine arteries, covered the stump with peritoneum, dropped it back, thus permitting the abdominal wound to be closed.

Panhysterectomy is the only operation worthy of consideration in cancer of the uterus. It became not infrequently the operation of election in large myomata when the cervix was spread out by the tumor, was diseased, or the seat of previous injury, which made its retention unfavorable for the future comfort and safety of the patient.

The discovery of the x rays by Röntgen in 1895 was probably the most striking and farreaching revelation of the age. What must have been Röntgen's sensation, when he accidentally saw the skeleton of his hand? Did he then appreciate the possibilities of this discovery? That it dawned upon him as a valuable revelation, is evident from the promptness, with which he made it known to the medical profession. Its value was at once recognized and its employment has developed a branch of medicine, useful not only in diagnosis, but in treatment as well.

A year later Becquerel described the remarkable radiant energy displayed by a sample of uranium, similar in its action to the x rays. Mme. Curie found that the radiation from the *salts* of uranium exceeded many times that obtained from the original metal. Their experiments led to the discovery of radium. The separation of radium from pitchblende has been the greatest and most notable contribution made to science by any woman.

(To be concluded)

Contributors to the Science of Medicine

Dr. William Beaumont

As is in keeping with a new country, some of the brightest lights of American medicine and surgery have been backwoodsmen. Marion Sims, who did much to develop the science of surgery on this continent, was a backwoods practitioner who came to be regarded as the leading clinical surgeon of his day. Ephraim McDowell, who also hailed from the backwoods and who did his wonderful first operation of ovariotomy, "far from the madding crowd," was a good second to Sims, and together they may be said to have founded the modern science of gynecology.

William Beaumont was another backwoodsman who was largely instrumental in revolutionizing knowledge of the physiology of digestion. He laid the foundation of the building upon which the brilliant Russian Pavlov placed the coping stone. Beaumont's experiments settled once and for all time the chemical nature of the digestive process, a subject which had puzzled physiologists from the days that Réaumur and Spallanzani first made researches in that direction. Before the results of Beaumont's investigations were made known knowledge of the physiology of digestion was of the most elementary character. Beaumont was the pioneer physiologist of this country and the first to make a contribution of enduring value.

William Beaumont, the third child of Samuel Beaumont, was born in Lebanon, Conn., November 21, 1785. His father was a frugal, thrifty New England farmer who at that time plowed his land with wooden plows drawn by oxen, sowed his grain broadcast by hand, cut it with a scythe, and threshed out the grain with the old fashioned flail. He lived sparely, went to bed and got up early, his clothes were homespun and almost proof against wear and tear and time. These New Englanders had strong religious and political views, and practised what they preached. In this straitlaced puritanical atmosphere young Beaumont was brought up and educated in the school in Lebanon under a teacher by name Tisdale, who for many years conducted the

school in such a way as to make Lebanon famous in New England.

When Beaumont was twenty-one years of age he left his father's roof and came to the village of Champlain in New York State, distant but a few miles from the Canadian frontier. He was well educated and was entrusted with the village school which he conducted for three years. In 1810 he crossed Lake Champlain to St. Albans, Vt., where he became apprentice to Dr. Benjamin Chandler and was thoroughly drilled in the duties and routine of a country practice of those days. He spent two years there never wasting time, reading the best books on medicine and surgery on which he could lay his hands, dissecting when the opportunity offered, seizing every occasion to do a postmortem, making careful notes, preserving his case records, and learning from the experience of his master. When he had completed his apprenticeship the "Third Medical Society of the State of Vermont, as by law established," granted him a license to practise.

In the war of 1812 he joined the army of the North as surgeon's mate. In 1813 he suspended duty for a time and began the practice of medicine it Plattsburgh, but soon returned to the army. In 1815, after peace had been concluded, he resigned from the army and entered into practice at Plattsburgh in partnership with another army surgeon, Dr. G. Senter. They also opened a store containing a "general assortment of drugs, medicines, groceries, dye woods, etc., which they calculate to sell on liberal terms for cash or approved credit." A few months later they dissolved partnership on account of Dr. Senter having to go South, and the firm became Beaumont and Wheelock. In 1820 he again joined the army and was commissioned by President Monroe on March 18, 1820, post surgeon of the army. He was immediately ordered to Fort Mackinac, on the northwestern frontier.

In 1822 he first came across that "old fistulous Alexis," then young, by whose means he was to make his famed investigations. In the summer the Indians and voyageurs were returning to Fort Mackinac, a station of the American Fur Company, with the results of the winter's catch. A gun was accidentally discharged in the retail store of the company and a young voyageur dropped to the floor, with a cavity in the left upper abdomen large enough to admit a man's fist. He was a young French Canadian about nineteen years old, whose name was Alexis St. Martin. The wound healed but the orifice could not be closed, and after seven months from its occurrence, the county refusing any further assistance to the patient, Beaumont took him into his family from motives of charity and a disposition to save his life, or, at least, to make him comfortable. St. Martin continued to improve in health until in 1825 the idea of carrying on a series of experiments on the stomach of St. Martin seems to have occurred to Beaumont. He began to realize the importance of the case and the opportunity vouchsafed him for learning essential scientific facts with regard to the physiology of digestion.

At or about this time he wrote the following description of the case which is recorded in the excellent life of Beaumont by Dr. Jesse S. Myer. "He will drink a quart of water or eat a dish of soup, and then by removing the dressings and compress, can immediately throw it out through the wound. On removing the dressings I frequently find the stomach inverted to the size and about the shape of a half blown rose. Yet he complains of no pain, and it will return itself, or is easily reduced by gentle pressure. When he lies on the opposite side I can look directly into the cavity of the stomach and almost see the process of digestion. I can pour in water with a funnel, or put in food with a spoon, and draw them out again with a syphon. I have frequently suspended flesh, raw and wasted, and other substances into the perforation to ascertain the length of time required to digest each; and at one time used a tent of raw beef, instead of lint, to stop the orifice, and found that in less than five hours it was completely digested off, as smooth and even as if it had been cut with a knife."

In the fall of 1824 Beaumont sent a complete report of the case to Surgeon General Lovell, who had it published in the *Medical Recorder* early in 1825. It was first published as reported by Lovell, but a correction was inserted in the same journal at the end of the year. In the meantime Beaumont found that his complete isolation in such an out of the way place as Fort Mackinac militated seriously against successful experiments. Not only were there no facilities for research but there was not a physician within a radius of many hundred miles from whom he could receive suggestions or with whom he could interchange ideas. Accordingly, he applied for an Eastern post and was transferred to Fort Niagara, where he continued to carry on his experiments, when they were interrupted by a most unexpected occurrence.

While on a visit to his family at Plattsburgh where he intended to exhibit St. Martin to some of the medical scientists of the day, the latter disappeared suddenly. It is supposed that the nearness of the Canadian border and the scenes of his boyhood proved too strong a temptation to St. Martin who took "French leave." However, Beaumont sent a series of experiments that he had made to the publisher of the *Medical Recorder*. This series of experiments numbered four, in which he noted the length of time required for the digestion of various articles of food suspended in the stomach by a silk string, which he could introduce and withdraw at pleasure, thus registering the changes in these substances from time to time. He determined "the natural warmth of the stomach" by introducing the glass portion of a thermometer marking the height of mercury on the glass and then placing it on the graduated scale. He compared the length of time of digestion of certain articles in the stomach and in vials containing gastric juice at the body temperature, agitated from time to time to imitate the gastric peristalsis. He found that the digestion took place more rapidly in the stomach than in the vial after the first half hour, that some meats digested more slowly than others, because the texture were closer than others. As Dr. Myer points out, even these incomplete experiments assured him that the old theories of maceration and putrefaction were insufficient to explain the processes that he had observed, and that the gastric secretion possessed innate solvent powers.

He was again moved, this time to Green Bay, Mich., an outpost of the fur trade where the prevailing conditions were similar to those at Mackinac. It is interesting to note that Beaumont was a staunch believer in vaccination and vaccinated voyageurs and Indians *con amore*.

In the early part of 1825 St. Martin was located. He had married, was poor and miserable, living about fifty-seven miles from Montreal. Four years from the time he left Beaumont, St. Martin returned to him with a wife and two children. During the time that he had been absent he had supported his family by the almost incredibly hard work of a voyageur, and his stomach and side were in much the same condition as when he left. He now entered Beaumont's service, who continued experiments interruptedly until March, 1831. During this time St. Martin did a great deal of hard work, became the father of more children, and enjoyed as good health and as much vigor as men in general. Moreover, he subsisted on crude food in abundant quantities, except when on prescribed diet for particular experimental purposes and under special observation. In these three years Beaumont made a series of valuable experiments, a detailed account of which there is no space to give. It may be said, however, that throughout the entire series of experiments he was suspending various articles of diet in the stomach, noting carefully the time required for the digestion of each and concluded this series of experiments with a series of ten, intended to demonstrate if possible "what effects were produced by the bile and pancreatic juice when added to chyme." It is needless to state that he arrived at no satisfactory conclusion concerning the bile and pancreatic juice. He concluded that the experiments showed plainly the solvent properties of the gastric juice and that its operation is that of a chemical agent.

Again the experiments were interrupted, as, with the consent of Beaumont, St. Martin returned to Canada. Soon after this Beaumont was at Fort Crawford, Michigan, to which post he had been ordered, where he underwent two experiences, a campaign against the Indians, and one against cholera. He also had experience of malaria and jotted down some notes on *The History of the Intermittent Fever* as it prevailed at Prairie du Chien in the summer and fall of 1830."

In 1832 the Indian war ended and the cholera epidemic was under control. Beaumont made his way to Plattsburgh and had not been there long when St. Martin appeared on the scene according to promise when the most remarkable contract ever known was drawn up between these men. This agreement provided that St. Martin should sell himself to Beaumont for a year to act as servant and for the purpose of experiments, the payment therefor to be board, lodging and all expenses and in addition $150. Beaumont had intended to spend a part of his furlough abroad but the authorities so curtailed it that he decided to spend it in Washington.

Between December 1, 1832, and March 1, 1833, 116 experiments were recorded. It seems that Alexis, who was immoderately fond of alcohol, somewhat spoiled the results of some of the experiments by his indulgence, as there is found in connection with one of his experiments that "the diseased appearance of the stomach at this examination was probably the effect of intoxication the day before." In 1833 he succeeded in enlisting the assistance of two of America's leading scientists, Robley Dunglinson, professor of physiology in the University of Virginia, and Benjamin Silliman, professor of chemistry in Yale University, and largely through them his investigations and results became known to some of the prominent men of science in Europe. In September, 1833, Beaumont published a book which was very favorably reviewed which contains an account of his experiments and deductions therefrom.

After this time he had a checkered career. He conceived the idea of obtaining aid from the Government to reimburse him for expenses incurred already and to enable him to continue his experiments. In spite of the support of the surgeon general and that of his scientific friends Congress refused to consider his appeal. This refusal was no doubt largely owing to ignorance, the members of Congress not being able to appreciate the importance and significance of a true knowledge of the physiology of digestion. Disappointed but not discouraged by this setback and heartened by the fact that his experiments had made of him an international character he determined to proceed with his attempts to solve further the problem of digestion. But again St. Martin proved a stumbling block as he did not come to meet Beaumont at Plattsburgh according to promise and no communication could be made with him.

At this time Beaumont had been transferred to Jefferson Barracks, St. Louis, a post which he found little to his liking, and at his solicitation was transferred to the arsenal where he was able to carry on private practice. Dr. Thomas Lawson had been appointed surgeon general and was not willing to allow Beaumont the facilities for experimental work or for work outside his official duties that his predecessor had allowed and the result was that Beaumont resigned from the army and thus ended his brilliant military career of more than twenty-five years.

While in private practice in St. Louis Beaumont in 1846, and at intervals up to the time almost of his death, negotiated to obtain St. Martin but never succeeded. In March, 1853, while returning home from a visit to a patient late in the evening, he slipped on ice covered stone steps, striking his head violently when he fell, and although his injuries were considered slight he never recovered completely. A few weeks later, on April 25th, he died, and thus closed an exceptional career.

Beaumont was essentially of the scientific mould. He had the inquisitiveness of the discoverer. He was not content to take for granted what other men had said but was ever on the lookout to find out the why and wherefore. In the words of Osler, the highest praise that we can give is to say that his life fulfilled the ideal with which he set out, and which he so well expressed in the sentence: "Truth, like beauty, is when unadorned adorned the most. And in prosecuting these experiments and inquiries I believe I have been guided by its light." St. Martin lived for twenty-eight years after Beaumont's death, but only a few unimportant experiments were made on him. He died at the age of eighty-three.

Editorial Articles

A FORGOTTEN WORTHY

We have called attention in these pages to the many great and influential preachers of hygiene and sanitation who were not physicians; such as Lord Bacon, Montaigne, Locke, Wesley, DeQuincey, Spencer, Beecher, and others of importance. None of these apostles of health stood out more boldly than the Reverend Charles Kingsley, though, after fifty years, he is remembered only for his *Westward Ho, Hypatia* and *The Water Babies.* Few know of him in the rôle of preacher of sanitation, of ventilation, of pure water supply, of safe sewage disposal and as a powerful pioneer advocate of health in all schools. Few indeed would guess that half a century ago he published a book on *Health in Education,* in which he prophesied that the teaching of the laws and practice of health "will, in some more civilized age and country, be held a necessary element in the school course of every child, just as necessary as reading, writing and arithmetic; for it is, after all, the most necessary branch of that 'technical education' of which we hear so much, namely, the technic, or art, of keeping alive and well." He went on to say: "The science of health, now so utterly neglected in our curriculum of socalled education, ought to be taught—the rudiments of it at least—in every school, college and university."

"I would make men and women discontented, with the divine and wholesome discontent, at their own physical frame, and at that of their children. I would accustom their eyes to those precious heirlooms of the human race, the statues of the old Greeks; to their tender grandeur, their chaste healthfulness, their unconscious, because perfect might: and say—There; these are tokens to you, and to all generations yet unborn, of what man could be once; of what he may be again if he will obey those laws of nature which are the voice of God."

In an address on Thrift, delivered to a society of women, he says: "Let me ask you, ladies, with all courtesy, but with all earnestness, Are you aware that more human beings are killed in England every year than at Waterloo or at Sadowa? Are you aware that the great majority of these victims are children? Are you aware that the diseases which carry them off are for the most part such as ought to be specially under the control of the women who love them, pet them, educate them, and would in many cases, if need be, lay down their lives for them? . . . It is a duty, one of the noblest of duties, to see that every child that is born into this great nation be developed to the highest pitch to which we can develop him, in physical strength and beauty as well as in intellect and virtue.

"We talk of the loss of human life in war. We are the fools of smoke and noise; because there are cannonballs and gunpowder, and red coats, and because it costs a great deal of money, and makes a great deal of noise in the papers, we think—'What is so terrible as war?' I will tell you what is ten times, and ten thousand times, more terrible than war, and that is—outraged Nature. . . . Nature, insidious, inexpensive, silent, sends no roar of cannon, no glitter of arms to do her work; she gives no warning note of preparation; she has no protocol, nor any diplomatic advances, whereby she warns her enemy that war is coming. . . . By the very same laws by which every blade of grass grows, and every insect springs to life in the sunbeam, she kills, and kills and kills, and is never tired of killing till she has taught man the terrible lesson he is so slow to learn, that Nature is only conquered by obeying her."

THE PROGRESS OF MEDICAL SCIENCE

During the past year medical science has progressed satisfactorily in several directions. It seems that in the field of biochemistry research will be most productive of results. Another field rich in potentialities and possibilities is that of comparative pathology, a branch of the study of disease which has been greatly neglected. In Great Britain much interest is being taken in this subject. Chairs have been established, or at any rate facilities and opportunities for gaining knowledge in this branch of science have been provided at some of the medical schools. The Zoological Society of London, under the terms of the charter, engaged to advance zoology and animal physiology. In the discharge of these obligations the society has taken recently two steps, the institution of a Fellowship of Comparative Pathology, jointly with the London School of Hygiene and Tropical Medicine, and of an Aquarium Research Fellowship. The only limitation laid down is that none of the animals in the London Zoological Gardens shall be used for the purpose of vivisection.

It may be said that it has long been recognized that the material supplied by zoological gardens offers remarkably wide scope for scientific investigation. Up to the present time, however, the work done has been chiefly in anatomical research, particularly in its possible bearing on systematic zoology. So long ago as the year 1865, when Huxley first became a

member of the council of the London Zoological Society, a prosector, whose duty it was to make postmortem examinations on the animals that died, was first appointed. The first prosector did some pathological work, but his successors did little or nothing in this line.

What can be accomplished and how rich are the opportunities have been amply demonstrated in the researches undertaken privately by Sir John Bland Sutton, president of the Royal College of Surgeons. While there has been a pathologist on the staff of the London Zoological Society since 1903, none of the holders has been a full time worker, and the investigations conducted by them have produced no important results. In this connection it may be pointed out that in Philadelphia, where the most consecutive and elaborate work on comparative pathology has been carried on, Dr. Herbert Fox, who made the postmortems in the Zoological Gardens, held a post in the university. Dr. H. H. Scott, the recently appointed Fellow of Comparative Pathology of the London Zoological Society and who, by the way, has distinguished himself especially by his investigation of the pathology and the discovery of a satisfactory treatment of sprue, will devote himself solely to research, and thus has been given a unique opportunity by the Zoological Society and the London School of Hygiene and Tropical Medicine.

By investigations made on the lower animals, knowledge of certain branches of medical science, to wit, embryology, anatomy, and parasitology, has been furthered greatly. In a like manner much may be gained in the study and understanding of human disease and veterinary medicine from comparative pathology. All the mammals have a more or less close family relationship and there is a less definite although obvious connection between them and birds, reptiles, and fishes. There may be and most probably are diseases and conditions of ill health peculiar to particular species, as for instance, man and the anthropoid ape.

The field of comparative pathology, however, in which useful knowledge is most likely to be gleaned, is the study of different phases exhibited by the same disease in different animals. Animals of one species may show a different form of a disease common to the species at large from the form exhibited by animals of another species, and by comparing these various aspects, a great deal may be learned of the history of the origin and distinctive character of the disease. Indeed, by the study of animals in a state of captivity, approaching perhaps in some degree the manner of life of man in a state of civilization, some facts may be learned of the socalled diseases of civilization, from many of which primitive man living in a state of nature somewhat resembling that of wild animals, is said to be and to have been immune. There appear to be such infinite possibilities in the study of comparative pathology pursued under fairly favorable conditions, that some of the secrets of the origin of disease which have baffled for so long the persistent efforts of investigators to lay bare, may at last be disclosed.

SEX AND CIVILIZATION

Psychology has come to the front—its zealous adherents might say, has come into its own, in recent years. The followers of Freud abound and many of the obscure complaints from which a somewhat neurotic generation suffer are treated by psychoanalysis. Paul Bousfield is prominent and in his latest work, *Sex and Civilization,* he brings forward some speculations and views of an uncommon nature. In it he discusses the position of women in England, where they are unfavorably situated from an economic viewpoint, and while admitting that, to some extent, this is the result of prejudice and legal disability, asks the question whether if prejudice and legal disability were completely swept away, would woman in general be able to take a place in the economic world in any way equal to that of man.

Of course, most people would answer that for two reasons she would be unable to do this: firstly, on account of her physical disabilities, and secondly, because of her temperamental disabilities. The author doubts the validity of both these reasons and in the book he marshals his arguments in support of these dissentient opinions. He endeavors to show that neither her physical nor temperamental disabilities are really so great as is commonly supposed and that given a different upbringing the sexes would be much more nearly on a plane of equality. He argues that the existing system of rearing and educating the sexes tends to emphasize their innate qualities and characteristics, mental and physical, and to confer on the male sex the dominance. He holds that male dominance is not in the best interests of society and the race.

So far as psychic disability of the female is concerned Bousfield says that research into the matter tends to show that this is chiefly due to waste of sexual energy. The main psychic difference between man and woman in this respect being connected with the fact that the man largely concentrates his erotic energy on what may be termed the normal acts of sex, which occupy but a little time and consume but a comparatively small amount of his psychic energy. On the other hand, the woman's sexual activity remains in an infantile form that is

spread throughout her whole life in such a way as to take up an immense amount of time with a corresponding expenditure of energy. This concentration on sexual matters is due chiefly to the repression which conventions of civilization have forced upon her from early childhood, and to the lack of provision for nonerotic outlets for her impulses and psychic energy for which the male is given ample opportunities for gratifying and dissipating. Thus it is contended in the book that the differences physical and temperamental between the sexes are purely artificial, man made in fact, which can be usefully overcome by the proper application of psychological research to the education of future generations.

Stop or hinder the continual leakage of energy which is the bane of civilized woman and the woman will be of equal capacity with man. That is to say, provide equal conditions for the two sexes, both during youth and adult life. Girls are not to be distinguished from boys by dress or to be taught that they belong to the weaker sex, nor boys to be inculcated with the notion that they are to show special marks of courtesy to members of the opposite sex. In short, the sexes are to be brought up, educated and live in exactly the same manner. Women are to be as free to make love and propose marriage as men, occupations are to be open to both sexes on strictly equal terms, and lastly the canons of morality from the sexual point of view are to apply with equal force to both sexes and no stigma is to be attached to the illegitimate child.

Bousfield presents his case vigorously and plausibly and with several points that he brings forward there is general agreement. For example, the difference in physical strength and endurance between the sexes is no doubt exaggerated. In endurance woman is superior to man in many respects. It is obvious, indeed, that it is folly to bring up girls as if they were tender plants and it is wise to encourage their participation in healthy games and in vigorous out of door exercise. But it is quite as obvious that the average woman is considerably less muscular than the average man and it seems doubtful whether living the same life as a man during generations would bring woman up to his physical standard. Physiologically and anatomically there is a difference between the sexes which appears to give to the man a physical superiority which he will retain to the end. Intellectually again, man seems to be on a higher plane than the woman, although woman's handicap in upbringing may account largely for her apparent inferiority.

Few women are original and they are almost wholly lacking in inventive genius. In fact women have rarely displayed genius in any phase of human endeavor. Talent of a very high order is fairly common in women, but genius of the first order is almost unknown. However, Bousfield does not intend his book as a final statement on a most fascinating subject, but rather as a suggestion of lines for further research to those who may follow. The book should act as an urge to others to pursue similar investigations.

BRAIN WEIGHT IN RELATION TO GENIUS

Discussion has been waged with regard to the relationship of the size of the brain to genius. Examples of brains of celebrated men have not decided the question as some of these have been heavy and others light brains. At the postmorten made recently on that great Frenchman, Anatole France, Felix Regault made an investigation on the brain and has contributed some notes on its weight. Anatole France was a tall and well built man, and the weight of his brain, which is given by Regault as 1-017 grams, did not express its quality. The average weight of the male brain in English tables is a little over 1-350 grams and in French textbooks is given at 1-390, so that the brain weight of Anatole France was considerably below the average.

It is obvious then that in this case the common belief that the weight of the brain bears a definite proportion to the scope of genius was not exemplified. Autopsies of distinguished men reveal so many variations in the weight of the brain that no deductions even of a general character can be made.

Regault does note that the convolutions of the brain of Anatole France were specially marked and the furrows deep. Only the most important of the furrows between the convolutions appear early in embryonic life, namely, those representing folds in the entire thickness of the brain wall. As the other convolutions appear, they are separated by furrows on sulci of a fairly constant character, but considerable differences within limits are found not only in individuals, but even in the two hemispheres of the same brain. As it is clear that the convoluted condition of the surface admits of a great increase of the grey matter without the sacrifice of large additional space, so it is reasonable to suppose that the number and extent of the convolutions, as well as the depth of the intervening sulci, should bear a direct relation to the intellectual powers of the individual.

There is evidence from the consideration of many postmortem examinations that such is the case, and the weight of the brain of another great Frenchman, Gambetta, is being quoted in support of the generalization, as Gambetta, like Anatole France, was found to have a comparatively light brain, with many well-defined convolutions separated by deep sulci.

CHRONIC DISEASES AS A HOSPITAL PROBLEM

The Public Health Committee of the New York Academy of Medicine in its report on The Hospital Situation in Greater New York, calls attention among other things, to the lack of institutional facilities for chronic patients and points out that even in New York city the institutional accommodations for these patients are inadequate. The obligation which the community owes to the chronic invalid has never been brought into proper focus and has never been properly defined. This state of affairs is not peculiar to New York city, but is countrywide. The interest of those most intimately concerned with community health and hospital problems is just beginning to be attracted to the subject. Several communities have attempted to formulate policies in regard to the care of the chronic sick, but there have been few facts available to serve as a guide.

One of the most important reasons for public indifference and for the chaotic state of mind in regard to this subject is the fact that no effort has been made to define what is meant by the chronic invalid and to visualize him and his needs as an individual. A patient who is chronically incapacitated by disease is ordinarily classed as an incurable and consequently it is tacitly assumed that expert medical care will be of no benefit to him and that so long as he receives food and lodging and the most elemental care, either at home or in a custodial institution, the community has discharged its obligation to him. This view is commonly current, not alone among the people at large, but also among physicians and others who are active in general hospitals and in other organizations that minister to the medical and economic needs of the community.

Consequently, the patient suffering from a chronic disease is cared for, if at all, in a haphazard manner and, when institutional care becomes necessary, is placed wherever he can gain admission, quite irrespective of whether or not the institution can serve his needs. The majority of patients with chronic diseases have found refuge in private homes for incurables, in municipal and county almshouses and in homes for the aged and infirm. A scant minority are accommodated in well organized hospitals for chronic diseases. Many who need institutional care must remain at home.

Not only is there an insufficiency in the number of beds for chronic cases, but also an inadequacy in the type of institutional care that is provided. There must be recognition of the fact that about seventy-five per cent. of these patients require intensive medical and nursing care, which can be given only in an institution having the equipment and organization of a general hospital. Custodial care, such as is provided at present in homes for incurables and almshouses, is inadequate in only one quarter of the cases.

Selfinterest, as well as humanity, demands that steps be taken for the correction of these conditions. Many of these patients can be rehabilitated if the effort is made and the means are provided. Instead of being permanent community charges many, after prolonged treatment, can be discharged to their homes.

At present, largely from ignorance, public opinion is dormant on this problem. It would be highly desirable to have a representative committee undertake a detailed survey of this situation and give the widest publicity to the results of its investigation.

RICKETS

Many diseases are diseases of civilization, but one of the most obviously so is rickets. When man lived in the open with a natural diet rickets was unknown. Dr. Joseph Garland contributes to the *Boston Medical and Surgical Journal,* March 26, 1925, a most strikingly rational article on rickets. He points out that civilized man has shut himself up into houses where the sunlight cannot reach him, and has substituted for a natural abundance of diet a diet of concentrated, preserved and altered foodstuffs. He also draws attention to the fact that the older school of clinicians recognized rickets empirically as well as its effective treatment. Indeed the use of codliver oil as an antirachitic agent has been known and practised for more than a hundred years as it was introduced into France for this purpose by Bretonneau, who lived from 1778 to 1862, while Guy in an article on the subject, *American Journal of Diseases of Children,* August, 1923, has traced the medicinal use of various fish oils for one purpose or another from the times of Hippocrates and Pliny through its entrance into the *British Pharmacopeia* in 1777 until the present time.

Discussion has waged around the etiology of rickets for long and during the past few years it has waged fast and furious. As said before the causes of rickets in a broad and general sense have been well recognized by clinicians for generations, but with the advent of bacteriology and the awakening of the scientific sense, the modern school of medicine has distrusted clinical observation however strongly fortified by experience and have demanded scientific proof. Numerous theories have been promulgated to account for rickets. Glisson, for example, believed it to be due to overeating. Heitzmann believed that the disease was owing to an acidosis which caused decalcification of the bones and is supported by Klose, Vogt and Pritchard. Others

have held that rickets is inherited, that it is the result of disturbance of the endocrine glands, or that it is the result of infection.

Findlay holds that the real cause of rickets is not yet known, but opines that the lack of fresh air and exercise and light are the chief factors in its production. A considerable number of French clinicians have asserted that rickets is a manifestation of congenital syphilis and autointoxication. Clement writing in the *Franco-British Medical Review,* January, 1925, thinks that a syphilitic etiology is highly debatable, but that unsuitable diet seems to be a factor. Mellanby, as a result of experiments, stated that the condition is probably owing to a lack of vitamine A and the British Medical Research Council somewhat prematurely identified the lacking factor as vitamine A. American investigators, McCollum and his colleagues, then established the importance of the rôle played by calcium and phosphorous in the pathogenesis of rickets and Orr of the Rowett Institute, Aberdeen, carried these investigations further. Shipley, Park, McCollum and Symonds suggest the possibility of two main kinds of rickets, a low phosphorus rickets with approximately normal calcium, and a low calcium rickets with approximately normal phosphorus.

As Clement points out in the article referred to already there is some evidence that osteomalacia may be related intimately to rickets if not identical, evidence from India seems to point in that direction. Clement suggests it would be of interest to know if the same curative effects could be obtained in osteomalacia by the ultraviolet rays, solar or artificial, as in rickets. Garland holds that light rays are the chief factors in the prevention and treatment of rickets, but unlike some light enthusiasts does not believe that diet is an almost negligible factor. In his opinion the antirachitic or x factor as contained in foods, and especially in codliver oil, is the second great agent in the prevention and treatment of rickets.

In conclusion, although the exact cause or causes of rickets are as yet undiscovered, it is known how the condition may be prevented or prevented from developing. And as Garland says, "for all practical purposes, our knowledge concerning its causes and our knowledge concerning its control are much as they were a century ago, for they were very complete then, in their fundamentals. Sunlight and its substitutes and codliver oil and its substitutes will prevent rickets and cure the disease once it has become evident, but to use a homely adage, an ounce of prevention is worth a pound of cure." Of course in the prevention of rickets good housing plays a great part and rickets will never be abolished so long as slums exist in large cities.

The feature of Garland's commonsense paper is that clinical observation matured by experience is still one of the greatest assets of a physician.

PERIODONTOCLASIA

The dentist has his long names as well as the physician. Periodontoclasia is used now, among the more knowing and exact, for pyorrhea, and, according to a dental surgeon, this disease "has had forty or fifty other names," none of which helped much in its diagnosis or cure. This writer continues: "More ignorance in dental diagnosis has been hidden behind these names than can be encountered in all the rest of dentistry combined. It has latterly been used as a bugaboo to frighten ignorant people into purchasing nostrums that have no place in the home care of the teeth. The term signifies an inflammatory pathological condition of the tissues infesting the roots of the teeth as well as the periosteum itself."

It is only about a quarter of a century since clinicians began to look their patients in the mouth so far as the condition of the teeth is concerned, and when the average hospital and dispensary case was so examined the findings were not pleasant to look upon. Clinical material in medical schools is chiefly constituted of the flotsam and jetsam of society who are ill because uncared for, and without proper care become ill. Periodontoclasia is, with them, the rule, which only goes to prove what the above dentist further says: that this condition "is never found in the mouths of people who are well. It is a symptom of anything which alters the physiologic balance of the circulation, and these may vary from some simple type of metastasis to a simple toxemia.

"At the beginning the natural power of resistance will prevent infection, but as the etiological disease increases in severity this is more and more diminished until finally infection gains a foothold, to be followed by any of the numerous types in which periodontoclasia is manifested. From this it is self evident that pyorrhea is never a disease *de novo,* but always a symptom of some disease."

And arthritis and other affections blamed upon this disease of the roots of the teeth? They are certainly not to be blamed upon pyorrhea. The same cause is at work and the removal of the diseased teeth does not remove the cause, though it may in some instances, perhaps, remove storage places of infectious material and postpone other decay. The mouths may be filthy but the blood and lymph back of the mouth is every whit as noxious, even if the badness be as invisible as carbon monoxide is invisible. The cleaning of a bad mouth is only the beginning of conversion to health.

News Items.

Memorial Library.—The library of the late Dr. Julius Parker Sedgwick, mainly on pediatrics, has been presented to the University of Minnesota, as a memorial.

Tuberculosis Hospitals Desire Pianos.—The New York Tuberculosis Association is anxious for gifts of pianos, especially for the twelve institutions directly under its supervision.

Use of Insulin.—A new decree in Germany classes insulin, including all pancreas extracts for injection, among the remedies for which a physician's prescription is required.

Chinese Medical Association.—The tenth anniversary of the National Medical Association of China is being celebrated. A campaign has been started to raise $100,000 for headquarters in Shanghai.

Memorial to Doctor Fletcher.—A recently completed high school in Asheville, North Carolina, has been named in memory of the late Dr. Marshall Hall Fletcher, a former president of the State Medical Society.

Study of Crime in Children.—New York University and the Children's Village are planning courses of study of crime in children, for executives and workers of institutions, to begin in September, under the direction of Leon C. Faulkner.

Gift of Radium.—The will of the late Dr. Edward L'Hommedieu McGinnis, New York, leaves his electrotherapeutic machines and a tube of radium to the Crocker Institute for Cancer Research, of Columbia, to be used under the direction of Dr. Francis Carter Wood.

Course at Strasbourg University.—A course in dermatology and venereal diseases will be held from September 12th to November 7th, at Strasbourg University, under the direction of Dr. L. M. Pautrier, to whom application should be made at 2 Quai St. Nicolas, Strasbourg, France.

Memorial Hospital.—The Bahnson Memorial Infirmary, built in memory of the late Dr. Henry F. Bahnson, of Winston-Salem, North Carolina, was presented to the Salem Women's College, at commencement time. Doctor Bahnson was president of the state medical society, and of the state board of health.

Institute for Biology.—Johns Hopkins University is to have a new institution for research in general problems of biology, especially population problems and the duration of life and its control. The institute will be financed by the Rockefeller Foundation, and will be under the direction of Raymond Pearl, Ph.D.

Faculty Changes at Jefferson Medical College.—Dr. Francis X. Dercum and Dr. Edward F. Hansell, of Jefferson Medical College, have been appointed emeriti professors of their departments, and active work taken over by Dr. Edward A. Strecker, as professor of nervous and mental diseases, and Dr. William M. Sweet, as professor of ophthalmology. Dr. P. Brooke Bland, of Philadelphia, has been appointed professor of obstetrics, and Dr. Norris Wistar Vaux, clinical professor of obstetrics.

Philadelphia County Medical Society.—The board of directors of this society announce the purchase of a permanent home—the old George C. Thomas estate at the corner of Twenty-first and Spruce Streets. The former art gallery of the building is to be altered into a meeting place accommodating about five hundred and fifty. The cost price was $125,000.

Guggenheim Fellowships.—Among those receiving fellowships for research study abroad, from the John Simon Guggenheim Memorial Foundation, are Dr. Percival Bailey of Peter Bent Brigham Hospital, Boston, for research in diseases of the nervous system, in Paris; and Dr. Edwin W. Schultz, of Stamford University, for study of bacteriophagy, in Egypt.

American Electrotherapeutic Association.—This association will hold its thirty fifth annual session September 15th to 18th, at the Hotel Drake, Chicago, Ill. Papers will be read by the leading men in the field of physical therapeutics and by invited guests of national reputation. A demonstration of actual technic of application of the various physical modalities will be given. There will be a complete exhibit of the latest electrotherapeutic apparatus and accessories. All legally licensed physicians are welcome and detailed program can be obtained by addressing Dr. Richard Kovacs, secretary, 223 East sixty-eighth Street, New York.

Doctor Rushmore Honored.—Dr. John D. Rushmore, of Brooklyn, was guest of honor at a luncheon, and was presented with a gold headed cane, to mark the completion of fifty years of practice. Doctor Rushmore is the emeritus professor of surgery at the Long Island Medical College Hospital. Dr. John O. Polak presided, and Dr. Frederick Tilney made the presentation.

New Convalescent Home.—A gift of one million dollars and two hundred acres of land at Greenwich, Connecticut, has been received by St. Luke's Hospital, from Mrs. Harriet M. Arnold, of New York, for a convalescent home. Half of the money is to provide buildings, and the other half is to be used as a permanent endowment fund. The gift was made without restrictions, but the request was made that a chapel be provided in the buildings.

Resolutions on Death of Doctor Dann.—The following resolution was adopted by the New York Eye and Ear Infirmary:

Resolved, That the Board of Surgeons of the New York Eye and Ear Infirmary records with profound sorrow the death of its late colleague, Dr. Nicholas R. Dann, who has faithfully served the Infirmary for the past twenty-five years. The Board of Surgeons extends to the bereaved widow its sincerest sympathy.

EDWARD B. DENCH, M.D., *Chairman*,
ROBERT LEWIS, *Secretary*.

Graduate Courses in Gastroenterology.—Two courses in gastroenterology—preliminary and practical—are to be given at Columbia University, by Dr. John Leonard Kantor, of New York. The preliminary course will be given from July 1st to 21st, repeated August 3d to 21st; and the practical course from July 22nd to August first, repeated August 22d to September 2d. Each course includes rontgen ray demonstrations; and the practical course will include clinical conferences on actual cases, with opportunity to assist in or perform the various manipulations necessary.

Fellowships in Neuropsychiatry.—The University of Pennsylvania, Graduate School of Medicine, announces five fellowships in neuropsychiatry, established by the Commonwealth Fund of New York. The fellowships are established for a period of three years from October 12, 1925, and will be for approximately $2,200 a year. The plans are for one year fundamental, one year practical, and one year investigative work. Application should be addressed to the Dean, Graduate School of Medicine, University of Pennsylvania, Philadelphia.

Medical Education Survey.—A Commission on National Medical Education has been appointed to make, under the general direction of the American Association of Medical Colleges, a five year study of medical education in this country. It is hoped that when the study is completed, legislatures passing laws regarding medical education and practice will have the advantage of well devised standards for guidance. No specific curriculum will be prescribed, however. Dr. Willard C. Rappleye, at present director of the New Haven General Hospital, will be executive head of the commission, and the other members are President A. Lawrence Lowell of Harvard, President Ray L. Wilbur of Stanford University, President Walter A. Jessup of the University of Iowa, Chancellor Samuel P. Capen of the University of Buffalo, Sir Robert Falconer, president of the University of Toronto; Dr. Walter L. Bierring of the National Board of Medical Examiners, and former Dean George Blumer, of the Yale Medical School.

Personal.—Dr. W. B. Brinsmade of New York has been appointed a Chevalier of the Legion of Honor by the French government. He was officially cited by General Pershing for meritorious and conspicuous service.

Dr. Fred H. Albee of New York has been appointed chairman of the American Committee of the International Medical Congress of Industrial Accidents and Diseases, which holds its next meeting in Amsterdam, Holland.

Dr. Louis Faugères Bishop, Jr., and Kathleen Sinclair, both of New York, were married June 20th at St. Thomas's Church.

Dr. Howard Buchanan, medical missionary for the United Presbyterian Board of Missions in the Sudan, who was blinded by a sandstorm on a trip to a nearby mission station, has returned to his home in Philadelphia, for treatment.

Dr. Hyman I. Goldstein, of Camden, New Jersey, was nominated as democratic candidate for coroner for Camden county; he has been elected vice-president of the Camden Federation of Jewish Charities, and president of B'nai B'rith at the June meeting.

Book Reviews

REJUVENATION

Theory and Practice of the Steinach Operation. With a Report on One Hundred Cases. By Dr. Peter Schmidt (Berlin). And an Introduction to the English Edition by J. Johnston Abraham. London: William Heinemann (Medical Books), Ltd., 1924. Pp. 150.

Rejuvenation. The Work of Steinach, Voronoff, and Others. By Norman Haire, Ch. M., M.B. New York: The Macmillan Company, 1925. Pp. 223.

The literature on the subject of rejuvenation and the Steinach operation has recently grown considerably and the latest contributions in English are the two books listed above.

Peter Schmidt's book is a translation and adaptation of his original German publication, somewhat enlarged, with the bibliography completed and containing reports on nearly one hundred cases in which the author operated. Schmidt, who is practising at present in China, is considered the foremost German exponent of the rejuvenation method of Steinach. In the first chapter, he gives a general survey of the most important publications dealing with the endocrinology of the sex glands and with regeneration by means of implantation and vasoligation. He reviews Steinach's work in which evidence of the dependence of the secondary sex characters on the internal secretion of the generative gland was adduced. The Leydig cell theory is discussed at length and the point of view of Steinach and his school, as compared with that of his opponents, is clearly defined. In Schmidt's opinion, the question is no longer, "Has vasoligation an effect?" but "Why has vasoligation an effect?"

A number of publications dealing with practical experience of the Steinach operation are discussed in this chapter and a number of cases operated in and reported by Lichtenstern, Benjamin, Chetwood, Klika and others are cited; likewise various animal experiments and the results of animal rejuvenation. The question of whether the generative portion of the testicle is the hormone producing tissue or whether this function is to be ascribed to the interstitial tissue is decided in favor of the latter theory. The pros and cons are reviewed in the same thorough and enlightening manner as in the original German.

In the second chapter Schmidt deals with the clinical picture produced by vasoligation in men and describes eighty-four cases of his own in detail. In chapter three he summarizes the clinical results and comes to the conclusion that decided benefits are derived in the somatic as well as the psychic life of the patients.

As the main indication for the operation, Schmidt mentions the extensive field of old age and its accompanying phenomena. Another large field for which the operation is indicated, he refers to as "single or polyglandular insufficiency" and the manifestations of such dysfunctioning. Psychic disturbances connected with wrong functioning of the sex glands offer frequent chances for success since the improved output of sexual hormones have a decided influence on the central nervous system. Lipschuetz's work in this regard is thoroughly reviewed. After mentioning prostatic hypertrophy as another frequent indication, he also considers the contraindications and finds that in cases of progressive tuberculosis and advanced hypertonia the patients should not be operated on.

A brief chapter on the results of the Steinach operation in men in relation to medicine in general and to sociology concludes the book. A very valuable and complete bibliography is added.

Schmidt's book is the only one written for the medical profession exclusively. Norman Haire's *Rejuvenation* deviates somewhat in this respect, as it is easily understandable to the laity also. Besides, it describes not only Steinach's researches and the results of vasoligation (the socalled Steinach operation) but also deals with the work of transplantation as advocated mainly by Voronoff. Haire also goes into the problem of rejuvenation in women by way of the transplantation of ovaries and through stimulating x ray treatments.

A brief general survey acquaints the reader with endocrine problems in general and the function of the sex glands in particular. Brief descriptions are given of the various methods employed to improve gonadal activity, explaining the nature of the homoplastic, autoplastic and heteroplastic methods.

In the second chapter, the rejuvenation experiments on animals are described in more detail. Complete case histories of Steinach's rejuvenated rats are given, as well as Voronoff's, Thorek's and Sand's experiences on animals. Sand's illustrated case of a senile dog is especially interesting. Unfortunately, recognition of Otmar Wilhelm's work on animals is missing. The next chapter, which is by far the longest in the book, describes the operation on human beings, complete case histories being reprinted from the original publications of various surgeons:

First, five cases of Lichtenstern of Vienna, who was the first surgeon who operated on Steinach's patients. His conclusions endorsing vasoligation are added.

Second, the work of Peter Schmidt, Berlin, is reviewed and a number of his cases related in detail with Schmidt's indications and suggestions in regard to the Steinach operation. After that follow four case histories of vasoligation reported by Walker and Cook (London), who disagree with Steinach's interpretation of his histological observations, but agree as to the practical results of the operation. Three of their patients were suffering from paralysis agitans and were distinctly improved. Reports of twenty-two cases in which operation was performed by Benjamin are reprinted with his technic, indications and confirmatory conclusions. After also mentioning the positive results of Knut Sand's human operations, Haire finally reports four of his own twenty-five cases in which he performed vasoligature. He gives his technic in detail. The results of the cases, which are described in a painstaking manner, are impressive and convincing.

The second part of this chapter deals with transplantation operations of testicles not only for the purpose of rejuvenation but also for the cure of eunuchoidism, loss of testicles and for the cure of

homosexuality. A highly interesting case of Lichtenstern is given in detail where castration and then transplantation of a normal testicle definitely cured a homosexual, whose inversion apparently was based on the production of a perverted gonadal hormone. Transplantation operations of Muehsam and Walker are reported, and likewise the work of Lydston is reviewed with eight case histories. Brief mention is made of Stanley's modified transplantation methods, Haire finally comes to the most important work, the work of Voronoff who does not use human material as the aforementioned surgeons, but choooses young adult monkeys, as donors of the testicles. His indications for testicular transplantation are: loss of testicles, infantilism, congenital testicular deficiency, senility, hardening of the arteries and dementia precox. Voronoff's technic and twelve of his cases are reported. A striking photograph of one of Voronoff's patients is also reproduced. The same procedure has been carried out in a number of cases by Thorek, partly through human and partly through ape transplantations. Thorek's indications and two of his cases are described.

The last part of this chapter deals with transplantation and stimulation of ovaries for the purpose of rejuvenation in women. Sippel in Berlin and Nattrass of Melbourne have done ovarian transplantations. Holzknecht, of Vienna, and Benjamin, of New York, have used mild stimulating x ray doses and the latter's cases with endocrine interpretation are reprinted. This entire chapter, although complete enough for the layman, omits a number of positive as well as negative reports, the authors of which can, however, be found in the bibliography.

The last chapter is devoted to criticisms and Haires's own conclusions, which are greatly abbreviated as follows:

1. The operation of vasoligation has no ill effects.
2. The operation is not universally successful.
3. Even in cases of organic diseases and advanced senility the operation often ameliorates the condition.
4. In carefully chosen cases, the operation may be very useful.
5. In successful cases many symptoms may improve, for instance, high blood pressure and insomnia. It may cause renewed growth of hair, improved capacity for mental work, and possibly increased sexual ability.
6. Unilateral ligations may often be quite sufficient. In some serious conditions, the bilateral operation may sometimes be necessary.
7. Transplantation of a testicle has no ill effects.
8. Transplantation of a testicle sometimes succeeds where vasoligation fails.
9. If successful, it may bring about the changes described under 5.
10. The testicle should be obtained from a human being if possible. One from a higher ape would be the next best substitute.
11. X ray radiation of the testicle is still in an experimental stage.
12. Transplantation of an ovary has no ill effects.
13. Transplantation of ovaries should always be carried out as a prophylactic measure, where the women's own ovaries have to be removed, owing to some disease.
14. Ovarian transplantation may be useful in senility, in deficient sex feeling and in certain cases of sterility.
15. X ray radiation of the ovary is still in an experimental stage. [The reviewer begs to disagree with this statement, owing to his own experience.]
16. It is impossible to decide whether any of these operations actually prolong life. There is absolutely no reason to believe that they shorten life at all.

Haires's book contains a bibliography and a very enlightening, unprejudiced and well written foreword by the author himself.

BACTERIOLOGY

An Introduction to Practical Bacteriology, as applied to Medicine and Public Health. By T. J. Mackie, M. D. (Glas.), D. P. H. (Oxford), and J. E. McCartney, M.D., D.Sc., Edin. New York: William Wood and Company. Edinburgh: E. and S. Livingston, 1925. Pp. 297.

This is not a textbook of bacteriology, but a practical laboratory guide or desk book for student use. Space is saved by the omission of practically all cuts, either of apparatus or of bacteria, a few explanatory diagrams only having been inserted. The technical directions are very complete, and cover all the work which a student would be expected to do in a course in bacteriology. It also includes what is usually omitted in American courses, and that is a certain amount of protozoology, the methods of staining Spironema pallidum in tissues, and some special technical procedures. It should be a very valuable guide for the student for whom it is intended.

TRANSFUSION

La Transfusion du Sang. Etude biologique et clinique. Par P-Emile Weil et Paul Isch-Wall. Paris: Masson et Cie, 1925.

This is an excellent and comprehensive monograph on transfusion. The introductory historical chapter is complete and makes fascinating reading. There follow chapters on the biology of transfusion, blood grouping, technic, and indications. A good bibliography, in which due weight is given to the American literature, concludes the work. American physicians will not quite share the authors' enthusiasm that transfusion is always harmless; nor will they agree that it is of major value in combatting surgical shock and acute infections. Nevertheless the book can be highly recommended as a scholarly, well balanced production, written by men with a first hand knowledge of their subject.

SPIROCHETAL RESPIRATORY DISEASES

Spirochetoses Respiratoires Stomatogenes. By G. Delamare. Paris: Masson et Cie, 1924. Pp. 143.

Under this title the author designates the respiratory diseases caused by the spirochetal organism producing often very severe nasal, laryngeal, tracheobronchitic, pleural, pulmonary, hemorrhagic and gangrenous symptoms. In this monograph the author brings forth the ideas concerning the origin of the disease, as having its primary focus most frequently in the mouth, but occasionally also in the upper respiratory tract. He gives an interesting history of his observations during the great epidemic of 1918-19, on which he has based all his conclusions. A careful reading of the chapters on etiology, experi-

mental pathology, symptomatology, diagnosis and prognosis, treatment and prophylaxis, and the epidemiology of the disease will give one a good idea of the present knowledge of this relatively new disease, so often mistakenly diagnosed as pulmonary tuberculosis. Particularly interesting are the observations quoted concerning the localization and geographical distribution of the disease during the epidemics of 1918-19. While, according to Castellani, immediately following the world war there were only three per cent. of spirochetal diseases in the Balkan regions, in Petrograd there were at the same time eighteen per cent.

Under prophylaxis the author recommends oral hygiene, particularly during grip epidemics, isolation of patients and disinfecting the expectoration. As treatment, besides building up the patient and attending to complications, he strongly advocates neosalvarsan. An extensive bibliography on spirochetal diseases, dating from 1906 to 1921, covering seven pages, is found at the end of the book, pages 3 to 8 containing an enumeration of 137 monographs on various medical subjects written by the author, Dr. G. Delamare.

THE ANEMIAS

Contribution to the Study of Pernicious Anemia and Aplastic Anemia. By Arthur Sheard, M.D. A Thesis Presented for the Degree of Doctor of Medicine in the University of Leeds, December, 1923. New York: William Wood and Company, 1924. Pp. 94.

This brief monograph covers the important facts and the significant literature of pernicious anemia and aplastic anemia. The author gives data from a study of fifteen cases of pernicious anemia. He presents evidence to show that in the postmortem study of the bone marrow in the anemias, it is important to examine many bones, for some of the long bones may show aplasia, while other ones show marked hyperplasia in the same case. In other words, the bone marrow does not undergo uniform hyperplasia throughout. The section on aplastic anemia consists of a review of the literature. The author believes that the majority of cases of aplastic anemia bear no relation whatever to pernicious anemia. Seventeen case reports and two excellent colored plates of the gross appearance of the bone marrow in various bones are included in the book.

The booklet may be recommended as giving a brief but adequate summary of the present state of our knowledge of pernicious and aplastic anemia.

OCTOPUS

The Matriarch. A chronicle. By G. B. Stern. New York: Alfred A. Knopf, 1925. Pp. 291.

It is not the Jewish family alone that holds its members in octopuslike toils, although the Jewish family has that long cherished tradition. Any solidarity of the past brings with it the conditions and problems so masterfully set forth. It is this quality of seemingly hammering at one point in a perfectly naïve and absorbed way, while the implications roll and flare from her anvil that makes Miss Stern such an excellent craftsman. The story is enough just by itself. What one learns from the story about her friends, the actors in this century of Jewish living, is enough. And what one gathers uneasily, maybe unconsciously at the time, to stick like burrs in one's memory, is also enough for the average intellect. Some get one dose, others get two, others get the whole exotic menu, not so much according to mental attainments, but according to what the readers' sore spots are on the tyranny-of-family situation.

The institution of matriarchy is thought by many to be the most primitive expression of the family. Matriarchy in the Jewish race is only to be expected since we have an ethnological group, compact, psychologically unchanged, since its first nomadic intrusions into the settled races. As a tribe, the race has remained defiant, often foolishly so. It is essentially a race ruled by cautious elders—policy dictated by the males, life dictated by the females. And life is always a few steps ahead of policy. So the race has been able to progress.

Early in the nineteenth century the elaborate chronicle begins. The network of family is already far flung like a spider's web. Miss Stern has chosen to follow one strain, the Rakonitz thread, a small family within a vast one, promoting individually what the race promotes. The eldest daughter of the eldest daughter steps each in turn under the shadow of the matriarchal cloak. In youth there is protest, an erratic burst to freedom—then acceptance and finally glory in the power thus conferred. Each matriarch—Babette, Anastasia, Toni—defies the world to find any similarity between herself and the almost demonic forbear. And yet there is no particle of change. Only as the generations spin out, new blood is gradually absorbed, tribal history becomes less real, less thrilling, less dangerous. The past gradually corrects itself, the normal healthy urge towards the future outweighs it.

A CANADIAN LOYALIST

Looking Backward. By George Sterling Ryerson, M.D. Toronto: The Ryerson Press, 1924. Pp. 264.

The author, who is well known in the United States as well as in his own country, Canada, through his career as professor of eye, ear and throat diseases in Trinity Medical College and the University of Toronto, traces his ancestry back to one of two brothers named Reyerzoon who in 1647 emigrated from Holland to America and settled in New York. At the time of the American Revolution, Dr. Ryerson's grandfather became a loyalist soldier at a very early age, and served with the British troops against the colonists.

Dr. Ryerson writes next of his own early life, his education in Edinburgh, Paris and Vienna, and his professional career in Canada. At the time of the Fenian raid in 1870, he was an ensign in a foot regiment, and was a regimental medical officer in the campaign of 1885 against the Indians. At this time he organized a bearer section and gives a most interesting account of his journey with it to the scene of battle.

The book contains a number of inaccuracies, some as to names, places and dates, and others in medical statements and facts. But these comparatively slight flaws detract very little from it as a vivid and comprehensive picture of the life of a man active in good deeds and of the time in which he has lived and worked.

Medicoliterary Notes.

Two recent publications from the British press which have received favorable reviews are *Workers' Education in England and the United States,* by Margaret T. Hodgen (Kegan Paul); and *Australian Totemism,* by Géza Róheim. (Allen & Unwin.)

* * *

The *American Journal of Public Health* is publishing regularly a selected public health bibliography which should be valuable to health officers and social workers.

* * *

A recent report issued by the Restaurant Owners' Association of New York states that not only are Americans the greatest meat eaters in the world, but that they also consume a greater number of eggs, about 150 being required annually per capita. Italians bring up the rear among flesh consuming peoples, with about twenty-four pounds a year.

The United States Bureau of Mines has recently approved the patent of a "selfrescuer," a pocket size gas respirator to protect the wearer from air contaminated with carbon monoxide fumes. The selfrescuer is to be worn chiefly by miners to enable them to escape safely from mines in which fires are burning or in which explosions have occurred. The instrument is constructed so as to provide protection from carbon monoxide for at least thirty minutes.

A parcels delivery has been organized in England by some of the girls and women who drove motor cycles during the war. It is called the motomessenger service. The drivers wear becoming uniforms and use side cars for the transportation of express material. Some of the girls are skilled mechanics and take care of their vehicles. The service has proved very popular both in the cities and the rural districts.

Because of the greatly increased prevalence of influenza and the common cold during the past few years, special studies of the subject have been made by a number of health organizations. One of the first reports to be published about these investigations is that of the U. S. Public Health Service as Supplement 48 to *Public Health Reports.* The study is entitled A Review of the Literature on Influenza and the Common Cold. The compiler and writer is Dr. J. G. Townsend.

Ainsworth Mitchell, British Home Office expert on documents, has recently come forward with proofs that the "casket" letters of Mary Queen of Scots are clever forgeries, probably by her secretary, Sir William Maitland, one of the subtlest and most accomplished rascals of his times. It will be remembered that it was on the testimony apparently revealed in these letters that Mary was sent to the scaffold. The casket included eight love letters to Bothwell, twelve love sonnets, and two contracts of marriage between Mary and Bothwell. Only the sonnets are considered by Mitchell to be genuine. By careful examination and study of handwritings, it was found that the casket letters could not have been written by Mary, and that they are written in a hand which is in many respects similar and sometimes identical with that of Maitland. This discovery means that the world's whole conception of the romantic Queen of Scots may have to be altered.

What is believed to be the first Chinese junk ever seen in New York sailed into the harbor of this city not long ago. It was manned by a captain, his wife and a small son. It took it two years to reach New York from China, and during the voyage the little boat passed through and resisted all kinds of weather.

The United States Department of Agriculture has resorted to the tattooing of hogs in order to trace the source of tuberculous cattle. The method is based on the belief that the swine become infected through contact with other animals. By the tattooing method hogs can easily be traced to the farm from which they come, since the mark is stamped in indelible ink and lasts throughout all the processes the carcass of the hog undergoes until it becomes pork, ham and bacon.

Brazil has rendered almost nil the danger of death from snake bites. An anti venom serum has been discovered by Dr. Vital Brazil, and the Butanan Institute has been established in Sao Paulo for treatment of bitten patients and also to act as a sort of exchange with farmers or individuals throughout Brazil by which they supply the institute with snakes and receive in exchange bottles of the serum. A special department of the institute sends out gratis a trap for catching the snakes without danger and also specially made boxes for their transportation, which has been made free by the railroads.

In Stuart Pratt Sherman's review of Werner's Brigham Young in a recent issue of *Books,* an amusing incident is cited to illustrate how Young was always at the disposal of his flock for good counsel and advice. "A woman rushed to him in tears to complain that her husband had told her to go to hell. Brigham Young looked at her solemnly and said, 'Well, don't go; don't go.' As advice it is perfect."

The greatest density of population in the United States is not found in New York, but in Rhode Island, which has 566 people to the square mile. Massachusetts comes next with 479 to the square mile. New Jersey is third with 420, Connecticut fourth with 286, and New York fifth with 217 to the square mile. The district of Columbia with 7,292 to the square mile stands in a class apart. The most thinly populated state is Nevada, with only seven tenths of a citizen for each square mile.—*N. Y. Times.*

One of the most heroic accomplishments in the annals of engineering has come to light in the account of a diver who, working singlehanded and in almost complete darkness, saved Winchester Cathedral in England by renewing its foundations. The task consumed almost five and a half years and was performed several feet below the surface in slimy soil and water. The building was foundering because it rested only on an eight foot layer of wet peat. The diver removed this material in sections, substituting concrete which he himself brought down and laid on a firm stratum of gravel, flint and chalk below the peat formation.—*Popular Mechanics.*

A test has been devised by Dr. Morris S. Viteles of the department of psychology of the University of Pennsylvania by which practically accurate discrimination between safe and unsafe taxi drivers can be made. This test is now being standardized for practical application in the near future. The system of examination will not only test the drivers for their ability to give the maximum amount of safety, but also for their courteous and intelligent service, capacity for attention to what is going on about them, ability to react properly in emergencies, and to estimate correctly the speed of moving objects.

The new Wisconsin General Hospital has recently announced the establishment of a three year professional nurses' training course to be carried on in connection with the College of Letters and Science of the University of Wisconsin. If at the end of the three years the nurse wishes to receive the degree of B.S. she may receive credit for her university work and complete the requirements for the degree. But she may receive her certificate of nursing after the required three years of nurses' training.

Abstracts from Current Literature

GENITOURINARY DISORDERS

Shock Reactions for Preoperative Testing of the Fragility of the Kidneys.—F. Leguen (*Bulletin de l'Académie de médecine,* October 21, 1924) points out that uremia is one of the most important factors in postoperative complications. It sometimes follows the oliguria which is often noted after operations, but in other instances occurs where there has been little or no reduction of urinary output and the operation has been carried out under regional or local anesthesia. Determination of the blood nitrogen and Ambard's coefficient is of some service as a preoperative test, but does not reveal the capacity of the kidneys to maintain their ordinary function under stress. The writer therefore tests the "fragility" of the renal function by means of a graded series of disturbing procedures, the first of which is ureteral catheterization—usually a preparatory measure in urinary cases. If an attack of fever and pain follows, the blood nitrogen and coefficient are determined again on the next day. Normally, these should both have been improved by the febrile reaction, but very frequently, they are found higher than before. Where such a spontaneous reaction is not obtained, the next step is the intravenous injection of 250 grams of thirty per cent. glucose solution. This injection, sometimes therapeutically useful, generally causes a chill, fever and notable systemic disturbance. The blood nitrogen and coefficient are then taken again, and often show a marked rise, while the general disturbance persists for several days. The writer's experience with these tests has shown that the blood nitrogen exhibits actual steadiness only in perfect health. In all those whose kidneys are no longer quite sound, the least disturbance reacts on the blood nitrogen. There is present, then, a renal fragility manifesting the low grade of nephritis common in the elderly, otherwise undetectable and the evidences of which are concealed by apparent health and the efficacy of strict dieting. If the glucose injection has caused a pronounced rise of blood nitrogen and general disturbance, immediate operation would entail undue risk. Patients with relatively normal blood nitrogen and coefficient sometimes show a rise of the former to 1.5 after the injection. Satisfactory tests do not insure absence of shock from the operation, but nevertheless afford a useful factor of safety. Where the reaction to the tests is poor, the operation need not necessarily be abandoned altogether, but should be postponed to a time when more favorable conditions exist.

The Four Hour Urine Test.—Henry M. Feinblatt (*Journal of Laboratory and Clinical Medicine,* June 1924) bases the present report on comparative observations on the specific gravity and the chloride content in 24-hour and four hour urine specimens from sixty apparently healthy medical students. The specific gravity readings were quite parallel in the two series; in more than half the specimens agreeing within two points, and in eighty-three per cent. the variation did not exceed four points; there was also a parallelism in the chloride output; in forty-five per cent. of the comparisons the difference did not exceed two gm. of chloride, and in eighty-two per cent. it was not greater than four gm. The four hour urine test is suggested with the idea of possibly replacing the routine examination of a single chance specimen, which has no value other than a quantitative one, and that it might serve as a substitute for the twenty-four hour examination when this specimen cannot be conveniently collected. If further comparative analyses on the other urinary constituents show a like parallelism, the four hour urine test would apparently be of value in meeting the conditions which suggested its employment.

Persistent Priapism.—Herdman Porter and R. H. Jocelyn Swan (*Lancet,* April 5, 1924) report a case of persistent priapism without any ascertainable cause. Intrathecal anesthesia caused no improvement in the condition. It was therefore decided to incise the crura of the penis rather than the penile corpora cavernosa. An incision was made obliquely downward and outward on the left side over the public ramus and the erector penis muscle was exposed and incised; the crus penis was much thickened. This was incised in the line of the wound, when dark, semiclotted blood slowly exuded. By pressure on the crus and on the penile corpora cavernosa a quantity of the same viscid dark blood was expressed, assisted by the passage of closed forceps into the crus in a forward direction. A similar procedure was adopted on the right side with the same results, and the whole penis became quite flaccid. Each crus was drained and the wounds were lightly sutured. The incision of the penile corpora cavernosa was not necessary. The patient recovered without the return of the priapism, though the erect penis was drawn to the side. In some cases it would appear that direct attack upon the crura is preferable.

An Unexplained Diazo Color Reaction in Uremic Sera.—On performing the indirect test (with alcoholic solution) of Ehrlich's diazo reaction on a number of patients suffering with nephritis, C. H. Andrews (*Lancet,* March 22, 1924) discovered an orange buff color, which gradually deepened during a period of twenty-four hours. In order to differentiate this from a possible azobilirubin reaction, an alkaline solution was added and a cherry pink color appeared, which disappeared after a few minutes. This finding was obtained in a number of severe uremic cases, but in no others. All of the cases had at least 220 mg. of urea per hundred cubic centimetres of blood. The uremias in these causes were of different origins and showed various clinical types, even without twitching or convulsions.

Retroperitoneal Catheterization of the Ureters.—A. Fullerton, (*British Journal of Surgery,* October, 1924) asserts that, in case it should be impossible to catheterize the ureters by the ordinary method, the ureter can be exposed for catheterization by stripping inwards the peritoneum after an incision in the parietes similar to that used for appendicectomy. In tuberculosis of the kidney, if a thickened ureter be found on one side, it need not be further disturbed. All that is necessary is to obtain a specimen from the opposite ureter. With careful technic and accurate suturing there need be no extravasation of urine. The actual quantity of urine secreted by a kidney can be ascertained by using a catheter of sufficient calibre to fit the ureter snugly, or by compressing the ureter round the catheter so as to avoid leakage by the side of the latter. The specimens so obtained are free from any contamination from the bladder contents.

Turpentine by Injection in Epididymitis.—A. A. Wren and J. L. Tenenbaum (*Surgery, Gynecology and Obstetrics,* October, 1924) submit their report of a hundred cases subjected to turpentine treatment exclusively to determine its therapeutic value. An emulsion of twenty per cent. turpentine in olive oil was administered upon the pelvic bone fascia at intervals of two days, each injection containing from one half to one cubic centimetre of the emulsion.

The injections were followed, in the majority of the cases, by analgesia and involution of the tumorlike swelling. In many instances a single injection sufficed to relieve the pain in from six to twelve hours after the injection. On the average, from three to four injections were administered in an individual case. The authors' experience, based on two years of careful clinical observation, leads to the conclusion that turpentine by injection is of value in the treatment of epididymitis.

Gonorrheal Calcaneal Periostosis.—C. C. Mape (*International Journal of Medicine and Surgery,* September, 1924) asserts that many ambiguities and inaccuracies of expression and description in modern medicochirurgical nomenclature originated in ancient mythical conceptions based upon intangible premises. The terms gonococcus, gonorrhea, gonorrheal, etc., being totally unscientific, inexact, absurd, should be discontinued. There exists no relationship between Neisserian invasion and osseous excrescences in any anatomical location, and such a contention is but an exhibition of pathological ignorance. Calcaneal periostosis, the only type hitherto presumed to be due to Neisserian invasion, occurs most frequently in individuals with a negative venereal history. The essential etiological factor responsible for osseous hypernutrition with resulting exostotic or osteophytic development remains unknown. The treatment of calcaneal periostosis is distinctly surgical, the administration of vaccines, phylacogens, etc., representing the acme of therapeutic absurdity.

Features of Urinary Calculi.—H. P. Winsbury White (*British Journal of Surgery,* July, 1924) makes a study of their radiographic features in relation to their chemical composition and structure, referring especially to renal calculi. Although holding that an exploratory operation is rarely justified when a radiogram is negative, he advises cystoscopy wherever possible for the reason that radiograms sometimes fail to demonstrate vesical calculi consisting largely of uric acid or ammonium urate. His chemical analyses lead him to conclude that the relative opacity of calculi of equal depth depends upon the atomic or molecular weights of their constituents. The opacity of a calculus is determined by the nature of its constituents, its structure, and its thickness. Calcium oxalate and calcium phosphate give very good shadows. They are very common constituents of urinary calculi. The high relative opacity is due to the high atomic weight of the calcium present in these salts. All the other common urinary salts give relatively poor shadows. They include the urates, uric acid, and triple phosphate. Cystine and xanthine also give poor shadows in the pure state, but of slightly more opacity than the foregoing owing to the sulphur they contain. It is rare for any of the foregoing substances to be the sole constituent of a stone. This applies to cystine as well as the more common varieties. There is frequently calcium oxalate or phosphate present. The figures of different observers giving the relative incidence of different salts in calculi have frequently been conflicting. Recent observers, however, are agreed upon the preponderance of calcium oxalate in renal and ureteric stones, and of uric acid and urates in bladder stones. Phosphate is found in larger proportions as a constituent of bladder stone than of renal stone. It frequently surrounds a nucleus of oxalate, or uric acid or urate. Stones of uric acid or urate in the kidney or ureter soon become mixed with calcium salts, after which they can be identified by radiogram.

Kidney Involvement from Prostatic Hypertrophy.—A. D. Bush (*Journal of Laboratory and Clinical Medicine,* August, 1924), in order to test the theory that kidney involvement accompanying prostatic hypertrophy is due to back pressure from the bladder through the ureters, performed experiments on dogs (whose vesical architecture is very much like that of man) with the object of obtaining a reflux if reasonably probable, which yielded no refluxes even under excessive intravesical pressures. A closely related origin of nephritic tissue and vesical trigone is shown by embryological studies. Clinical data show a closely coordinated innervation of kidney, ureter, and trigone; experimental data indicate that electric stimulation of the proximal end of the cut hypogastric nerve affects the functional activity of the kidney. From these several findings the conclusion is reached that uncomplicated kidney dysfunction, accompanying prostatic hypertrophy, is a condition primarily due to neural reflexes coming from the area of the trigone by way of the hypogastric afferent nerves and then out through the eleventh and twelfth thoracic autonomic nerves to the kidneys.

Undescended Testicle.—C. G. Mixter (*Surgery, Gynecology and Obstetrics,* September, 1924) says that operations for undescended testicle in childhood may be expected to yield seventy-five to eighty per cent. of satisfactory results; that is to say, the testicle remains in the scrotum and subsequent atrophy does not ensue. To attain this result, the spermatic circulation should be preserved and the cord lengthened sufficiently to allow the testicle to be placed in the scrotum without tension. In a certain number of cases in particular those of the intraabdominal variety, it will be necessary to section the spermatic vessels. Where this procedure is unavoidable, atrophy occurs in eighty five per cent. of the testes. It is indicated in only about ten per cent. of all cases. Atrophy may ensue where the spermatic vessels are not divided. This is probably due to accidental tearing of some of the trunks at operation or inclusion in the stitches, if the cord is anchored to Poupart's ligament. Operation may be undertaken at any age with the expectation of a good result, if the accompanying hernia becomes troublesome or other indications arise. The preferable age for operation is between five and twelve years. At an earlier age the structures are so delicate that injury to the spermatic vessels is difficult to avoid. Orchidectomy should not be done in childhood. Replacement of the testes in the abdomen should also be avoided on account of the risk of a future malignancy. In even the most difficult case, section of the spermatic vessels and transposition of the vas and its accompanying vessels behind the deep epigastric will make it possible to place the testis in the scrotum.

The examination of cases in which the patients were operated on in childhood with preservation of the spermatic circulation and have passed the age of puberty, frequently reveal on palpation a testicle that has apparently developed normally. From this series no light has been thrown on the spermatogenetic function of the undescended testis subsequent to an operation performed before puberty. It is hoped that later the bilateral cases of this type may afford some valuable data. In no instance has a recurrence of the hernia been observed.

Venesection Blood Transfusion in Anuria.—C. A. Bower and H. R. Trattner (*Surgery, Gynecology and Obstetrics,* August, 1924), draw attention to their success in the use of a repeated venesection transfusion method in a case of acute nephritis with anuria. They conclude therefrom that repeated venesection transfusion is a logical procedure in acute conditions interfering with the permeability of the kidneys, in that it lowers the amount of accumulated catabolic products in the blood, not only by frequent removal but also by repeated dilution of the remaining circulating blood. It is a more logical procedure than a single venesection transfusion, since it is inconceivable that the tissues could be detoxified for a sufficient length of time to admit of much benefit. It tides the patient over a critical period until the kidneys can again resume their function. It can be used as an accessory measure but should not supplant renal decapsulation which is a recognized useful procedure in nephritis. The frequency and number given in any case should depend upon the clinical condition of the patient, the blood chemistry findings, and the quantity of urine excreted in twenty-four hours. We ascribe an important rôle to repeated venesection transfusion in the recovery of our patient, since there was no tension that could be relieved by decapsulation, and no diuretic effect was obtained following the operation.

Renal Tumors.—G. Phillips (*International Journal of Medicine and Surgery,* July, 1924) finds that tumors of the kidney is generally of a most malignant nature. However, there is a period in the development of these tumors when they are clinically benign. Of the early signs urinary bleeding is the most important. This is the point when the practitioner's responsibility is greatest. A patient cannot be urged too strongly in the presence of this sign to consult the urologist immediately. Even then the amount of information to be obtained is not great and it takes one's every resource to arrive at a diagnosis. If the bleeding kidney can be identified, great progress has been made. Should the kidney shadow or pyelogram suggest even slightly a kidney tumor the writer is of the opinion that sufficient warant has been obtained to investigate surgically, and if simple exposure of the organ gives no information, then nephrotomy or even nephrectomy is indicated. By the latter procedure, of course, an organ not deserving it will sometimes be sacrificed—say a chronic contracted kidney, or a case of chronic nephritis, or one having a simple varix. But this risk is much less than allowing to remain a bleeding tender organ, the cause of which is unknown.

Before any attempt is made to remove a neoplastic kidney there should first be considered the practicability of performing a ligation of its pedicle, especially the vascular portion, by either the transperitoneal or paraperitoneal route. With that accomplished an operator may proceed with a free conscience with the nephrectomy, either through the same incision or by means of a lumbar incision.

Treatment of Stenosed Urinary Meatus.—A. L. Wolbarst (*International Journal of Medicine and Surgery,* September, 1924) discusses the pathology of this disease and recommends meatotomy for both acute inflammatory and non inflammatory conditions thereof. His operative technic follows.

A complete meatotomy requires that both external and internal orifices shall be incised to such an extent that a metal bulbous bougie with a caliber of 32 French can be inserted easily into the urethra, beyond the fossa navicularis. The incision is made in the middle line, usually along the floor of the meatus; when, however, the meatus is inferiorly situated so that an extensive incision along its floor will create an artificial hypospadias, it is desirable, in fact, necessary, to cut both superior and inferior margins of the meatus, thereby avoiding the creation of hypospadias.

Local anesthesia is employed, though in extremely sensi-

tive patients a general anesthetic may be necessary. Textbooks speak of producing anesthesia by the insertion within the fossa of a plug of absorbent cotton saturated in a one or two per cent. solution of novocain. This method has not been satisfactory in my experience. My personal preference is for the use of a much weaker solution—one eighth or one tenth per cent. injected into the tissue surrounding the site of the incision; this gives a much more satisfactory anesthesia.

It is a highly desirable practice to bring the mucous membrane of the urethra in contact with the skin by means of several catgut or horsehair sutures. This procedure usually produces a much more satisfactory result, diminishes bleeding and encourages rapid healing.

Vital Staining of the Bladder Mucosa in Man with Methylene Blue.—G. Huber-Pestalozzi (*Schweizer medizinische Wochenschrift,* September 18, 1924) was enabled to gain a better insight into the pathological processes in the bladder by filling the bladder with a five per cent. solution of methylene blue, preceded and followed by irrigation with a sterile normal salt solution. No discoloration was noted in five healthy male bladders, but the discoloration was found in five female bladders, which had never been diseased and were entirely asymptomatic, also in four cases of a previously existing cystitis (now asymptomatic) and in four cases of existing chronic cystitis. The region of the trigone was stained in the majority of the cases, chiefly females. The author maintains that this is not due to vital staining, but rather a discoloration of dead or dying cells, which are still adherent firmly to the tissue. Heretofore it has not been known that such desquamations could occur in practically healthy bladders. The process is the most intensive in the region of the trigone and its immediate vicinity (vesical sphincter), that is, in the region of the most marked mechanical work. The remaining parts of the bladder show this discoloration only rarely.

New Treatment for Tuberculosis of the Bladder.—Marion and Blanc (*Presse médicale,* March 7, 1925) have had very gratifying results with instillations of methylene blue into the bladder in the phenomena of cystitis accompanying renal tuberculosis, alike in operated and in inoperable patients. There are no contraindications to the procedure. Ten to fifteen mils of a warmed solution of methylene blue in normal saline solution are injected. The strength of the solution is one per cent. in average cases; in acute cases, or after the condition has been considerably improved, a 0.5 per cent. seolution is used. If the bladder contains much débris, it should first be cleaned out by irrigations. The instillation is repeated on alternate days in average cases and every three days in acute cases. Four or five instillations are sufficient to bring relief for a considerable time. It is better to resume the treatment when symptoms reappear than to employ protracted treatment. Methylene blue by the mouth must be continued at the same time. The drug acts both as an antiseptic and an analgesic. Inspection of the bladder shows that the drug becomes fixed exclusively in the diseased areas. There have been no failures of this procedure, which produces a rapid and excellent effect on frequency, pain in the bladder and urethra, and mild hematuria. The bladder capacity is notably increased. Improvement is less pronounced in crystitis with incontinence. One patient, who voided every half hour, was enabled, after three weeks, to hold his urine for six hours, although the case was one of bilateral renal involvement precluding nephrectomy.

Treatment of Chancroid with Tartar Emetic Solution Intravenously.—Herman Goodman (*Journal of Urology,* April, 1925) proposes the use of solutions of tartar emetic intravenously in the treatment of chancroid, following his experiences with this drug in the tropics in the therapy of granuloma inguinale. In his experience, the diagnosis of chancroid most often rests on clinical observation; absence of Spirocheta pallida on dark field examination; and absence of the socalled Calimato bacterium granulomatis of inguinal granuloma. The search for Ducrey bacilli in smears has not been fruitful, and the utilization of culture methods has not been routine. The Wassermann reaction is of negative aid. The patients have presented themselves for treatment after extension to the draining glands, and several after ineffective antisyphilitic treatment. Other patients had been under observation for urethritis because of a purulent discharge exuding from an acquired phimotic prepuce. Goodman uses the actual cautery knife to make a dorsal slit when indicated rather than the cold knife because of the possible danger of opening blood and lymph channels. Local cleanliness with soap and water, and immersion of the affected part in warmed mercuric chloride was insisted upon.

The innovation in treatment is the use intravenously of solutions of tartar emetic or antimony potassium tartrate. The drug is given in concentration of 1:100. A commercial sterilized one per cent. solution, standardized and biologically tested, contained in ten c.c. hermetically sealed ampoules, has been used. The initial dose intravenously has been five c.c. of the 1:100 solution, given once every second day or at longer intervals to once in five days. The number of injections has varied from four to eight. The dose may be increased by one c.c. at each injection, but no dose greater than twelve c.c. has been administered. There have been no ill effects.

The use of antimony potassium tartrate in chancroid is recited in case histories. It is hoped that the experiences of others will warrant further publication.

Leucoplakia of the Kidney Pelvis.—F. Hinman, A. A. Kutzmann and T. E. Gibson (*Surgery, Gynecology and Obstetrics,* October, 1924) report two new cases of this complication, which, together with other reported cases, lead them to the following conclusions:

1. Leucoplakia of the urinary tract may be defined as an epidermoid transformation of the mucosa, in plaques usually, with excessive keratinization and desquamation. The condition is generally associated with longstanding inflammation, calculus formation or other irritation, which seem to be contributory factors in its causation.

2. The etiology of leucoplakia is unknown. The most common theories are that it is a true metaplasia on the basis of chronic inflammation and irritation, or the biological process of adaptation to environment in the form of protective cornification; or that leucoplakia of the urinary tract arises on the basis of misplaced embryonal rests of primitive ectoderm.

3. Leucoplakia of the renal pelvis occurs about equally often in both sexes and it may occur at any age. The greatest frequency is in the fourth decade.

4. The symptomatology is that of urinary tract infection (cystitis, pyelitis, pyelonephritis, pyonephrosis) and urinary lithiasis, conditions with which it is usually assocated.

5. The treatment of choice is nephrectomy, since the disease is incurable and precancerous. Palliative measures, in the form of pelvic lavage, are probably beneficial only in subduing infection and in that way possibly delaying the progress of the condition. The value of radiotherapy is not known. Fulguration may be of value in leucoplakia of the bladder, but as yet no reports of its use have been found.

Nitrite Reaction in Urine.—Wilfried Loewenstein (*Wiener klinische Wochenschrift,* February 7, 1924) proposes a test from which practical conclusions may be drawn which are of importance to the specialist and simplify the work of the general practitioner. If alphanaphthylamin is added to a cloudy urine in a test tube, three different results may be observed: 1, the cloudiness may disappear without a change in color, as is the case in phosphaturia or carbonaturia (reagent contains acetic acid); 2, there may be a positive result, showing a cherry red discoloration and indicating the presence of infection with nitriteforming bacteria, such as staphylococci, colon bacilli, proteus, aerogenes lactis and others; 3, the cloudiness may persist without a discoloration. The latter finding is explainable only in combination with other tests. There may either be urinary retention, in which case the disintegration has taken place beyond the nitrites in spite of the presence of nitrite forming bacteria, or there may be an infection with nonnitrite forming bacteria, such as streptococci, tubercle bacilli and gonococci. It must also be taken into consideration that the appearance of the reaction may possibly have been inhibited in the presence of nitrite forming bacteria. In mixed infection (gonococcus plus nitrite forming bacteria) a positive result may be assumed to indicate the disappearance of the gonococci and the predominance of other varieties of bacteria. These results show that in the examination of cloudy urine the substitution of the Griess reagent (containing acetic acid) has advantages over the simple acetic acid test.

Unilateral Diuresis.—Andrew Fullerton (*British Medical Journal,* February 2, 1924) advances the theory that the diminution of the specific gravity of the urine on the affected side is of great value in diagnosis. A small irritating stone in the pelvis of the kidney may produce unilateral diuresis and aid in the diagnosis of renal disturbance in the absence of pus or blood in the urine. If the renal parenchyma is involved only slightly, the clinical picture resembles that of stone or early tubercle, showing an increase in the amount of urine of low specific gravity on the affected side. If the stone is associated with pyelitis, the specific gravity and the flow of urine soon become equal on the two sides after removal of the cause. Then the renal parenchyma is affected by disease or a neoplasm, the specific gravity is diminished on the affected side, but the flow is diminished with the progressive involvement on the affected side, until the sound kidney does most or all of the work, as in the later stages of renal stone, tuberculosis, pyelonephritis, cystic kidney, hydronephrosis, pyonephrosis and neoplasm. In essential renal hematuria the diminution in the specific gravity is less likely to occur on the affected side because of the absence of gross kidney changes. A difference on specific gravity on the two sides favors the diagnosis of new growth rather than the less serious complaint.

Risks of Prostatectomy.—Kenneth M. Walker (*Practitioner,* May, 1924) thus summarizes his paper. In all cases in which well defined signs of obstruction exist operative treatment is indicated with as little delay as possible, since the persistence of obstruction constitutes a menace to the kidneys. Even in the presence of associated lesions, such as those of the heart and lungs, and amongst those of advanced years, prostatectomy offers a better chance of survival than catheter life. The mere existence of enlargement without symptoms is not in itself an indication for operation, but it undoubtedly constitutes an indication for maintaining the patient under close observation in order that the earliest signs of obstruction may be detected. In all cases in which sepsis is present, or in which a careful investigation of the kidneys gives indication of impaired deficiency, it is absolutely essential that these complications should be dealt with by means of preliminary drainage before any attempt is made to enucleate the prostate.

Hereditary and Familial Nephritis.—J. Eason, G. L. Malcolm Smith and George Buchanan (*Lancet,* September 27, 1924) draw the following conclusions from their experimental investigations:

1. Nephritis may be hereditary, familial, or congenital, as shown by the cases described in the literature.

2. A familial predisposition to nephritis seems to exist in a series of cases instanced by the authors, and notably in two families.

3. In one family there was an association of apoplexy and nephritis, six members of the family being affected by one or both. The discovered onset was at or after middle life.

4. In the second family there were seven cases, of which five were discovered in childhood or adolescence. Four of the cases in this family were diagnosed within a few weeks of one another. That the actual origin was not recent, but of some years' standing, is evident from the fact that the arteries in three were thickened, the blood pressure high, and the nonprotein nitrogen of the blood high.

5. No definite etiological factor could be found in these cases to account for either the nephritis, high blood pressure, or thickened arteries. Syphilis is discounted by a negative Wassermann reaction in all cases. There is no history of scarlet fever or influenza in any of the cases.

6. In one case there is a definite history of chill immediately preceding the onset of the disease.

7. Pure growth of nonhemolytic streptococci were obtained from the blood and urine of two cases on admission to the hospital.

8. Blood cultures carried out four months later yielded no growths.

9. A streptococcus was obtained twice from the urine of one patient while in the hospital, and again on the return for a later examination.

10. A feature of note in primary cultures was the delay and feeble nature of the growth between the third and sixth day of incubation.

11. The types of streptococci isolated from the blood and urine were biochemically identical with those obtained from the teeth, tonsils, and tonsillar region. Such streptococci commonly live as harmless saprophytes in the mouth and throat, but may become parasitic and associate themselves with subacute infections.

12. In addition to the presence of intrinsic weakness causing a *locus minoris resistentiae* in the kidney, a possible extrinsic factor in the recurrent attacks of nephritis may possibly be due to streptococcal infections.

13. There is considerable evidence for the conclusion that the teeth and tonsils may be regarded as among the important primary sources of infection, and probable portals of entry for hematogenous infection. It is possible that repeated infections may occur at such times when the normal resistance of the tonsils and tissues is lowered from local or general causes. Such infections may exercise an exacerbating influence in the course of the disease.

14. The failure to confirm the result of the first bacteriological examination of the blood, and the negative findings in two of the cases, suggest a local infection producing disease by periodic systemic invasion—that is, a transient bacteriemia with rapid localization of the invading organism in such organs most susceptible to its power of invasion, resulting in a focal expression of infection. In the family studied the kidney appears to be singularly predisposed to infection and the most susceptible organ.

15. Experimental evidence is given on the causation of nephritis by a nonhemolytic streptococcus isolated from cases of subacute nephritis.

Fatal Azotemia with Histologically Normal Kidneys.—A. Lemierre, P. N. Deschamps and E. Bernard (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris,* June 19, 1924) all attention to the incongruity of cases of renal insufficiency in which nitrogen retention develops in the absence of edema or high blood pressure and with but slight changes in the urine. They report the case of a plumber aged twenty-four years, without anything suggestive in the past medical history, in whom diarrhea had been present for three weeks, followed by abdominal pain, vomiting and more copious diarrhea, restlessness and finally stupor. Admitted to a hospital at this juncture, the patient succumbed two days later in progressive coma with hypothermia. Blood examination on the day before death showed 5.3 parts of urea in 1000, and a few hours before death, 6.46 parts. Yet the kidneys were found practically normal macroscopically as well as microscopically. The only lesions found elsewhere were a recent infarct in the right lung and a few hemorrhagic suffusions in the stomach. The nitrogen retention had been more particularly a retention of urea, the latter having risen to over fifteen times the normal in the blood, and the residual nitrogen only to four times the normal. The outstanding clinical features of this case of apparent acute nephritis were the respiratory rhythm, hypothermia and the condition of the urine. The breathing was identical with the type described by Kussmaul in diabetic coma, being regular, with great amplitude of inspiration and noisy expiration; the rate rose gradually from eighteen to thirty-two per minute. The low temperature, 35.5° C., has been pointed to by several authors as a true symptom of azotemia. Instead of anuria or marked oliguria, with marked changes in the urine, as might have been expected, the patient yielded 600 mils of urine on catheterization on the day preceding death, and 500 mils on the day of death, and the bladder was found full at the autopsy. The urine was pale, clear, with but little albumin, and contained neither casts nor blood. The urea content of the urine on the last day was but 1.2 per cent., showing a reduced urea concentrating power on the part of the kidneys. The underlying cause of this serious disturbance of renal function in the absence of pathologic lesions remained obscure. Though the patient was a plumber, there were no clinical evidences of lead poisoning.

Relation of Gonorrheal Proctitis in Male Infants to Hospital Epidemics of Vulvovaginitis.—Albert H. Byfield and Mark L. Floyd (*Archives of Pediatrics,* October, 1924) show that rectal gonorrhea in male infants may occur in the course of a ward epidemic and not cause sufficient signs and symptoms to arouse suspicion that this trouble is present. Such infection may be the source of repeated late outbreaks when the epidemic is believed to have been stamped out. The rectal thermometer is probably the carrier. It is always well to check up in hospitals on the custom of taking temperature. Trays with individual receptacles for thermometers or individual containers for thermometers should always be used in baby's ward.

NEW YORK, WEDNESDAY, JULY 1, 1925

Medicolegal Notes.

PHYSICIAN'S TESTIMONY OF EXAMINATION BASED ON PATIENT'S STATEMENTS OF SYMPTOMS HELD INADMISSIBLE

Where one of the injuries claimed as resulting from an accident was defective hearing, a medical expert, who had made on the day preceding the trial an examination of the plaintiff for the sole purpose of testifying at the trial, testified that he had made a series of tests to establish whether the plaintiff had normal hearing, and whether his auditory nerve was normal, but that he was unable to reach a conclusion on these matters without the aid of subjective symptoms. The New Jersey Supreme Court held, Hutchinson v. Jersey Central Traction R. Co., 126 Atl., 482, that it was prejudicial error to admit the testimony of the witness as to the result of his examination so far as it included and was based upon statements made to him by the plaintiff as to the latter's symptoms and opinions.

EXPERT MEDICAL TESTIMONY IN MALPRACTICE CASES

In a malpractice case, the negligence consisting in leaving a sponge in the patient's abdominal cavity after an operation it was argued for the defendant that medical experts are the only persons qualified to testify whether an operation was negligently performed, and that the handling of the sponges in this case was but a part of the operation.

The Circuit Court of Appeals, Eighth Circuit, however, Laughlin v. Christensen, 1 Fed. (2nd) 215, holds that in such a case the testimony of medical experts is not essential. The court says that it is true that there is a large class of malpractice cases in which the question or matter under investigation is so intricate and abstruse, or so little understood, that ordinary jurors would in all probability know nothing about it, but must be guided by opinions of witnesses having special knowledge. In this class of cases the plaintiff fails to make a case for the jury, in the absence of testimony of a properly qualified expert witness.

The court goes on to say, however, that there are two other classes of cases dealing with the admission of expert testimony on the issue of negligence. 1. Those in which the question or matter under investigation is so simple that the jurors are as well able as experts to pass upon the same. Admission of expert testimony in this class of cases is held to be error. 2. Those cases in which the question or matter under investigation is of such character that the opinion of expert witnesses thereon, though not indispensable, may yet be of material assistance to the jury. In this class of cases the admission or rejection of expert testimony rests in the sound discretion of the court.

Furthermore, the court said, it is not a universal rule, even when the alleged negligence of medical men is under consideration, that testimony by experts is indispensable. In the "sponge" cases called to the court's attention, it said that it did not find one in which such a rule was laid down or applied. In the court's opinion, a scientific exposition of the subject was not necessary to enable the jury to pass upon the question whether the sponge was negligently left in plaintiff's abdominal cavity by defendant in the case before the court, no question of science being involved. The question whether defendant and his assistant did in fact count the sponges after the operation and find the same number as they had before the operation required no technical skill or special training to decide. The court was not called upon to decide whether expert testimony would have been admissible, if offered, on the part of plaintiff.

PROOF OF INTENT IN PROSECUTION FOR ILLEGAL SALE OF MORPHINE BY PHYSICIAN

The Circuit Court of Appeals, Fifth Circuit, holds, Williams v. United States, 294 Fed. 682, that, on the trial of a physician for violation of the Harrison Act by selling morphine not in the regular course of his professional practice, or for the treatment of any disease, but to satisfy the craving of an addict, it was proper to allow proof that the accused had either sold or administered morphine on previous occasions, as bearing upon his intent. "A practicing physician does not violate the act in question if he merely dispenses morphine 'in the course of his professional practice only,' but it is a violation of the law for a physician to dispense morphine for the purpose of gratifying the appetites of those addicted to the use of it. The evidence of other sales was therefore properly admitted to show knowledge and an unlawful intent. A dealer, as distinguished from a physician, is authorized to sell opium or its derivatives only upon a written order, and if he has not such order his intent is immaterial."

It was held unobjectionable for the indictment to describe morphine sulphate as morphine, by which name the derivative is commonly known.

LIABILITY FOR REQUESTED OPERATION ON DEFENDANT'S SON

In an action to recover for services as physician and surgeon to the defendant's son, where the petition charged that the services were rendered at the instance and request of the defendant, it was held, Bailey v. Yowell (Mo. App.) 266 S. W. 324, that whether the son was a minor or of full age was immaterial. Instructions that if the son was a minor and the father, the defendant, authorized another physician to take him to the plaintiff for treatment, or if they believed that the son was over 21 years of age and the father told the other physician to have the operation performed and he would pay for it, they should find for the plaintiff, were held not prejudicial to the defendant. A requested instruction which would have required the jury to find that the son was under age, and that the father had authorized the operation and agreed to pay for it, before they could find for the plaintiff, was held properly refused.

PHYSICIAN HELD NOT NEGLIGENT IN RELYING ON ATTENDANT TO WRAP HOT FLATIRONS PROPERLY

A physician called to attend a patient directed that hot flatirons be placed about her. A woman employed by the patient's husband to attend her wrapped up the irons and placed them in the bed. Two became unwrapped and the patient was badly burned. In an action against the physician for malpractice, the Minnesota Supreme Court held, Olson v. Bolstad, 201 N. W. 918, that the defendant was not chargeable with negligence in relying upon the attendant to wrap them properly.

HYPOTHETICAL QUESTIONS

The Illinois Supreme Court holds, People v. Pigatti, 314 Ill. 626, 145 N. E. 608, that it is proper to allow a hypothetical question to a medical witness although it does not contain all the facts in evidence in the case, where there is evidence in the case as to each fact stated in the question.

PRIVILEGED COMMUNICATIONS

The plaintiff in a personal injury case had received medical attention from a physician. Another physician was present, and at the request of the attending physician participated in the examination of the plaintiff. The Minnesota Supreme Court held, Leonczak v. Minneapolis, St. P. v. S. S. M. Ry. Co., 201 N. W. 551, that the information required by the latter physician was privileged within the Minnesota statute.

Multiple Stage Operation Versus the Immediate Excision of the Pathology*

FREDERIC W. BANCROFT, M.D., F.A.C.S.
New York

Since Lister's epoch making discovery of antisepsis, which showed the way to asepsis, the progress of surgery may be divided into three eras, namely: 1, the era of operative discoveries; 2, the era of mechanical advancement; and 3, the statistical era.

The first era, that of operative discovery, was the era in which many of our now standard operations were developed. This was undoubtedly the most fascinating period of surgery. Imaginative and master minds were constantly finding new fields. Men like Murphy and Halsted whose names are attached to many operations were the pioneers in that era.

The next era, the one of mechanical advancement, was in a way a retrograde one. The surgeon then became more of a carpenter. Elaborate mechanical aids were advocated for many types of surgical procedures. Many of these aids, such as elaborate bone plates, while remarkable inventions, were foreign bodies too large to be handled easily by the human organism. Probably the greatest advancements in this era were the mechanical devices invented for diagnosis. The cystoscope, the proctoscope and the bronchoscope have revolutionized the diagnosis in their respective fields. During this period, also, the x ray advanced still further the progress of diagnosis and treatment of surgical diseases.

The third era of which I wish to speak may be termed the statistical era. In it, through the study of mortality, statistics and analysis of the followup results, we have realized that many operative procedures, while successful surgically were failures in that patients either died subsequently or lived a life of discomfort. Codman, Crile and the Mayos have been pioneers in this country in this advance. A study of the gradually accumulated statistics of the present day extensive operations, which are the outgrowth of these three eras, reveals a relatively high mortality in many surgical procedures. Efforts have been made by all surgeons to reduce this high mortality.

We have come to realize that a patient must be prepared for operative procedure by gradations. Many patients, who would otherwise be lost, can be saved by following this line of procedure. The surgeon now must have some knowledge of blood chemistry, biology and physiology. He is no longer the carpenter who might be directed by the medical man to do a certain mechanical procedure. The surgeon must consider the individual patient and the disease in order to plan his procedure. It has been the tendency of all of us to attempt to remove obvious pathology, often at the sacrifice of the patient's life. It is much wiser to do frequent preparatory operations, eventually saving a patient than to do one large operation with subsequent mortality.

I thought it might be of interest for a gathering of this kind to review the various preoperative tests, preoperative treatments and multiple stage operations that have crept into surgery during the last few years.

If one begins at the head and works downward, one is surprised to see what a large group will be encountered. It is obvious that in a hasty résumé, many processes which would fall in this group will be omitted. If, however, we start at the skull we may begin with brain abscess.

1. *Brain abscess.*—Is fatal in a large percentage of cases but we have found that the mortality can be greatly reduced by doing a preliminary craniotomy, opening the dura and packing. This creates adhesions, and when later at a second stage the abscess is drained, the brain does not recede, further infection is not so probable, and meningitis may be prevented.

2. *Cervical adenitis.*—Much discussion has occurred in recent years between pediatrists and surgeons concerning the proper operative procedure in tuberculous adenitis where large tonsils are present. The present consensus of opinion is that it is wiser first to remove the tonsils, and later, if necessary, the nodes of the neck. It has been argued that if the nodes are first excised and the tonsils later removed, the damage to the lymphatic structure of the neck is too great. It has also been observed, clinically, that occasionally enlarged nodes recede after tonsillectomy. Preliminary x ray therapy is still in its development, and one must believe that in the future most tuberculous nodes should be treated for a period of time by x ray. Many operations will then be avoided.

3. *Thyroid.*—Undoubtedly the greatest progress

*Read before the Alumnæ Association, Lincoln Hospital, New York.

Copyright, 1925, by A. R. Elliott Publishing Company.

of many stage operations or preoperative therapy is exemplified in diseases of the thyroid. Mortality of exophthalmic goitre or toxic adenoma has been tremendously reduced. The basal metabolism test has given us a knowledge of the toxicity of a patient. Data derived from the basal metabolism and the clinical study of a patient with hyperthyroidism have shown us that certain patients will not stand a prolonged operative ordeal. Mann and others have shown that by administering Lugol's solution, we may reduce basal metabolism ten to fifteen points. At this stage one or both superior thyroid arteries may be ligated under local anesthesia with a relative impunity. The maximum gain from ligation of the superior poles of the thyroid persists for about three months, and then begins to decline. A thyroidectomy can be performed three months after ligation of the superior poles, and the patient saved. Often in the study of a toxic goitre we find it advisable to remove infected teeth and tonsils in the interval stage between ligation of thyroids and thyroidectomy. There is no question that some hyperthyroid patients can now be cured by surgery by multiple stage operations, where previously an immediate thyroidectomy would have been followed by serious consequences.

4. *Empyema.*—The war with its terrific operative mortality in training camps taught us a great deal about certain types of empyema. We have learned that in streptococcus empyema cases an early thoracotomy is almost always fatal. It is necessary to have a certain amount of pleural exudate with adhesions in order to stabilize the mediastinum. If we open the chest too soon, the heart and bloodvessels are dislocated by the collapse of the lung, and immediate death may occur. In these cases thoracentesis repeated frequently, with small amounts removed, can later safely be followed by a thoracotomy. In desperately ill children, with postpneumonic empyema, a preliminary intercostal thoracotomy under local anesthesia will reduce the operative mortality. At a later stage, when the child is safely over the acute empyema, a rib resection may be advisable. A word of warning should be offered, however, that the pendulum in acute empyema cases is probably swinging too far in the opposite direction. If operation is postponed too long a rigid thickened pleura prevents the expansion of the lung, and we have a chronic empyema, one of the most difficult problems of surgery to deal with. In chronic empyema, Keller has shown that multiple operations, removing portions of ribs at a time to obliterate the dead space, reduced the shock and therefore the operative mortality.

5. *Esophagus.*—For obstruction due to carcinoma of the esophagus, preliminary gastrostomy must frequently be done for feeding, and then if the carcinoma is considered operable, a preliminary stage is frequently done, exposing the esophagus, and freeing it, then allowing adhesions to be formed by the pleura, or a later operation may be done to attempt to reconstruct the esophagus.

6. *Biliary tract.*—The liver, one of the most important organs in the abdominal cavity, is an unexplored field in many ways in our knowledge of surgery. We must learn some test of liver function, which will indicate to us the patient's ability to react from operative procedure. In both thyroid and kidneys we have chemical means of determining the patient's operability. Some similar procedure must be discovered for the liver. It is to be hoped that the phenoltetrachlorphthalein test will eventually fill this requirement. The icterus index is a reliable means of estimating the amount of jaundice that a patient is suffering from. The clotting and bleeding times are aids in preoperative preparation. By the administration of calcium, serum or drugs like fibrinogen, we may prepare the patient so that later oozing may be avoided. Next to the thyroid the multiple stage operation in biliary tract diseases is most important.

In abscess of the liver or in echinococcus cysts, a preliminary operation is necessary to wall off the peritoneal cavity and produce adhesions. A secondary operation can then be performed without risk of implantation of daughter cysts or secondary peritoneal infection. Likewise, in the approach of a subphrenic abscess, if the pleura be entered, it is necessary to produce adhesions before opening the abscess.

Acute cholecystitis is a disease which has previously created a higher mortality than most surgeons realize. Some years ago it was our tendency at the New York Hospital to operate in all acute cases of cholecystitis, performing a cholecystectomy as one would an appendectomy in acute appendicitis. To my surprise in going over our operative statistics I found that our mortality was in the region of eighteen per cent. We have found that by delaying operation until the temperature subsides, and then performing a cholecystostomy, the mortality can be greatly reduced. While a cholecystectomy may be necessary later, the primary procedure will reduce the mortality. In a recent case where Dr. Murray drained the gallbladder in a gangrenous cholecystitis, the entire gallbladder later sloughed out. This patient would probably have been lost had he attempted a cholecystectomy at the primary operation. In cases of severe jaundice in poor risks where there is obstruction of the common duct by stone, a primary cholecystostomy under local anesthesia, to relieve the jaundice is frequently a wise procedure. At a later period, when the patient's general condition is improved, the stone may be removed with relative impunity.

7. *Stomach.*—In carcinoma of the stomach with pyloric obstruction in debilitated patients, a preliminary jejunostomy for feeding purposes may be performed. Also in certain cases of carcinoma of the stomach with pyloric obstruction, a two stage operation may be performed, first, a gastroenterostomy and at a later stage a partial gastrectomy.

8. *Appendix.*—It has long been recognized by surgeons, that in appendicitis with abscess, it is advisable to drain the abscess without seeking for the appendix. If one attempts an appendectomy the protective adhesions may be broken up and a general peritonitis result. Many of these cases are cured as the appendix becomes gangrenous and sloughs out.

9. *Intestinal obstruction.*—Most hospital clinics show a mortality of fifty per cent. from intestinal obstruction. It is a well known fact that these patients stand any operative procedure or mauling badly. In the severe risks, a preliminary jejunos-

tomy will often tide them over the danger period; particularly is this true when the obstruction is relatively high. A second stage operation may then be performed to remove the cause of obstruction.

In cancer of the colon, Erdmann and others have urged a primary cecostomy under local anesthesia. When the carcinoma is in the rectum or lower sigmoid, a two stage operation may later be necessary following cecostomy.

10. *Genitourinary tract.*—The work of Geraghty with the phenolphthalein test is one of the greatest advancements of surgery. It may be safely stated that the present genitourinary diagnosis with cystoscopic phthalein and blood chemistry examinations is nearer an exact science than any other branch of surgery. By this means we are able to determine the portion of the genitourinary tract affected and the function of one or both kidneys. In hydronephrosis or pyonephrosis cures may occasionally be obtained by inserting a ureteral catheter and, thereby, producing drainage. Even if this is not entirely curative, a secondary operation is safer and frequently less radical.

In prostatic obstruction we have learned that urea nitrogen and creatinin retention in the blood indicate the likelihood of death if a prostatectomy is attempted. We have learned that a preliminary insertion of a permanent catheter, or if this is not feasible, a suprapubic cystostomy for drainage will reduce the nitrogen and creatinin retention of the blood to such a figure that a secondary operation for prostatectomy can be performed.

11. *Skin grafts.*—The late results of Thiersch skin grafts for filling defects wherein there has been scar tissue have been very unsatisfactory. It has been shown that contractions do occur beneath the Thiersch graft. This is due to the fact that no fat or connective tissue is transplanted with the thin layer of skin. For this reason pedicle grafts have become popular. The tubular graft with the two or three stage operation has proved very successful in this type of cases. With this graft fat can be transplanted and there is little likelihood of severe contractions. The socalled caterpillar graft is a tubular graft that may be taken from a distant part of the body and moved upward to the field of operation by alternately cutting one or the other pedicle and replacing it in a prepared field, always approaching nearer the defect.

12. *Osteomyelitis.*—In closing it is necessary to say a word about acute hematogenous osteomyelitis. Previously radical operations were advocated for osteomyelitis. Some men even advised the excision of the entire shaft at the primary operation. Unfortunate results occasionally occurred as in certain cases there was no regeneration of the shaft, and later difficult bone transplant operations had to be performed. If osteomyelitis can be recognized at an early stage the simplest type of surgical drainage can be established as a preliminary step, traumatizing the medullary canal as little as possible. When the acute suppuration has subsided, occasionally sequestrectomies have to be performed, but in the majority of cases early operation and adequate drainage will shorten the stay of the patient in the hospital and prevent deformities.

CONCLUSION

The object of surgery is to cure patients. If by performing multiple stage operations we can reduce the mortality, and make patients more efficient citizens, we are justified, no matter how long the hospital stay. It is a great temptation for all of us, when we see a pathological process, immediately to attempt its excision or cure. If the patient is unable to stand this prolonged procedure, mortality may result which might otherwise be avoided.

100 East Sixty-sixth Street.

The Use of Dental Stent in Skin Grafts of the Middle Ear and Mastoid Cavities

J. PAUL DE RIVER, M.D.
San Francisco, California

The purpose of the radical mastoid operation is well known to us all but do we achieve the desired results in all cases, namely, the union of the external auditory canal, the middle ear, antrum and mastoid wound, into a common cavity, and the lining of this cavity with epidermis by the implantation of a flap from the external canal.

The necessity for skin grafting in the middle ear and mastoid cavity as a secondary procedure, following the radical mastoid operation, is apparent.

The plastic flap, used by a majority of otologists, works well in some cases. In my experience with over three hundred radical mastoid operations, epidermization of the cavity by the flap method is not always obtained. In such cases the use of the detached graft is indicated.

I am somewhat skeptical about the pedunculated graft of the flap operation, because pedunculated flaps must be thick. The attachment of the flap, held in place by sutures, throws tension on the pedicle. Passive congestion may ensue which results in death to all parts.

In dermic and epidermic detached grafts, the life of the graft depends upon its contact with the underlying surface. If thorough contact is obtained and the proper surgical technic carried out, the danger of the graft not taking is remote. Then the question arises of securing perfect approximation of these two surfaces. It is at this point that I wish to call attention to the use of the dental molding compound.

I have used this substance in two types of cases: First, in those cases where complete obliteration of the mastoid and middle ear cavities is desired, and second, in cases in which there is a persistent otor-

rhea, due to infection in the eustachian tube, and when it is desired to obliterate the middle ear orifice of this tube.

In the first instance, when it is desired to obliterate completely the mastoid and middle ear cavities, after having the wound prepared for the reception of a skin graft, a sheet of sterile dental molding compound is immersed in hot water for a period of thirty seconds. It is then taken out and allowed to cool, until it becomes flexible but not gummy. The compound is now packed into the mastoid cavity and middle ear and allowed to remain there until it hardens.

With this impression of the cavity the graft is then obtained, preferably from the thigh, taking enough epidermis to cover the cavities. It is then spread over the impression compound, raw surface outward, making sure that there is no turning in of the edges. This done, the molding compound, with the graft lying around it, is inserted into the mastoid wound and firm pressure applied, so that it will slip into place and approximation of surfaces be obtained.

The mastoid wound is allowed to remain open and a gauze pad is placed over it. Drainage is obtained through the external auditory canal by a gauze wick and a pressure bandage applied to the mastoid wound. The bandage is removed in four days, the pressure compound taken out and the wound closed under local anesthesia.

The second variety of cases is that in which the disease is confined to the eustachian tube and, after a thorough curettage, one desires to obliterate the orifice of the tube by skin graft. For this type the impression compound is introduced through the external canal into the middle ear cavity, and an impression obtained of the part of the cavity that is to be obliterated, namely, the eustachian orifice.

A skin graft is taken and placed over the impression compound, raw surface outwards. This is gently introduced through the external canal into the middle ear cavity. Firm pressure is made so that approximation of surfaces is obtained. The compound is held in place by cotton packs, together with a pressure bandage over the external canal. After four days the bandage is cut and the impression compound gently withdrawn from the external canal with a pair of forceps.

The success of a skin graft on any part of the body depends upon the approximation of the surfaces and this can be secured only through pressure. For this reason I use the aforesaid method.

Chronic Prostatitis With Special Reference to Its Focal Aspects*

JACKSON K. HOLLOWAY, M.D.
and WILLIAM H. VON LACKUM, M.D.

Rochester, Minn.

(*Concluded from page 24*)

Case III.—A man, aged thirty-three, came to the clinic September 18, 1924, complaining of rheumatism, weakness and loss of weight. Without apparent cause, in 1918, stiffness and swelling developed in the right knee. The course was intermittent until 1921, when following influenza a generalized arthritis developed, which continued until admission. The patient had had gonorrhea in 1914, and was apparently cured in six weeks. He was twenty pounds underweight, and tired easily. Repeated examinations of the lower urinary tract had not revealed disease. Urine was normal except for pus; Wassermann reaction negative. The hemoglobin was seventy-nine per cent., the erythrocytes numbered 4,490,000 and the leucocytes 7,900. Röntgenograms revealed periapical lesions of the teeth 2; thickened lungs with retracted pleura (right); and hypertrophic arthritis of the knees and elbows. The prostate was small, regular, symmetrical and firm. The right globus major was infiltrated.

After provocative treatment, prostatitis 2 was diagnosed on the fifth examination. The arthritis improved promptly; the patient gained five pounds following ten treatments given in fourteen days. Six weeks later he was continuing to improve, and felt better than at any time since 1918. Tonsils and infected teeth were not removed.

Case IV.—A man, aged twenty-four, came to the clinic July 10, 1924, complaining of swelling of the left foot, weakness, and loss of weight. In 1918 the left foot was slightly injured; it remained swollen, and was tender at intervals. In 1919 tonsillectomy was followed by marked swelling and pain for two weeks. In 1921, following removal of a third molar, which was abscessed, the symptoms all disappeared. In January, 1923, he began to lose weight and declined from 150 to 123 pounds in six months. In July, 1923, pain and stiffness invaded all the joints of the left foot, and the ankle and knee became large and swollen. Periodic swelling and tenderness in the left lower extremity induced varying degrees of difficulty in walking. He continued to lose weight. He complained of nocturia; denied gonorrheal infection.

The Wassermann reaction and examination of the urine were negative. The hemoglobin was seventy-eight per cent., the erythrocytes numbered 4,920,000, the leucocytes 7,600. The tonsils had been cleanly removed. Röntgenograms of the sinuses and teeth were negative. There was arthritis of the left knee and ankle. The prostate was small, smooth, regular, nonsensitive, and boggy 1. The first examination of the prostatic secretion revealed an occasional pus cell; the second examination five to ten pus cells, with occasional small clumps, the third examination 400 to 500 pus cells.[1] After

*Submitted for publication March 31, 1925.

[1]The counts of pus cells refer to the average high power field.

thirty-three treatments in sixty days the patient was greatly improved.

CASE V.—A man, aged thirty-six, came to the clinic October 8, 1924, complaining of pain in the left leg of one and one half years' duration. With out apparent cause eighteen months before, an aching pain began in the ischial region extending down the back of the thigh to the knee and occasionally to the foot. Pain was never entirely relieved. The patient denied having gonorrheal infection.

The Wassermann reaction and examination of the urine were negative. The hemoglobin was 78 per cent., the erythrocytes numbered 4,430,000 and the leucocytes 6,400. Röntgen ray examination of the teeth was negative. The tonsils were septic 2, with fluid pus in the right. The prostate was enlarged, firm, regular and symmetrical. The first and second examinations of the prostatic secretion following provocative treatments revealed an occasional pus cell; the third examination twenty to thirty pus cells, and the fourth thirty to thirty-five cells.

There was gradual improvement after thirty treatments in thirty-six days. The patient was entirely free from pain.

CASE VI.—A man, aged sixty-four, came to the clinic August 11, 1924, complaining of weakness and bladder trouble. He had lost weight and strength gradually for six years. The total loss of weight was thirty pounds. He had had lumbar and sacral backache for three years; dysuria and slow stream for one year which was without acute retention. There was no history of gonorrheal infection.

The Wassermann reaction was negative. The urine contained a trace of albumin, an occasional hyalin cast and pus cell. The hemoglobin was 40 per cent., the erythrocytes numbered 1,970,000 and leucocytes 12,000. The differential count was normal. The erythrocytes revealed slight anisocytosis and poikilocytosis. Röntgen ray examination revealed a periapical lesion and an old lesion in the right upper lobe of the lung. The tonsils were atrophic. The prostate was enlarged 2, smooth, regular, and tender. The prostatic secretion following provocative treatment showed 400 to 500 pus cells on the second examination.

After fifteen treatments in thirty days the patient had gained ten pounds and his general health was excellent. Dysuria and nocturia had improved greatly.

In August, 1924, the hemoglobin was 34 per cent., the erythrocytes numbered 2,130,000 and leucocytes 12,000. On September 28 the hemoglobin was 74 per cent. and the erythrocytes numbered 4,010,000.

CASE VII.—A man, aged thirty-eight, came to the clinic June 30, 1924, complaining of pain in the small of the back. In February, 1923, following an attack of tonsillitis severe lumbago had developed, necessitating a stay in bed of two weeks. When he got up pain recurred in the right hip and back, and he was on crutches for about four months. Several teeth had been removed and tonsillectomy performed in November, 1923. His condition remained unchanged until January, 1924. Since then he had gradually become worse; pain had extended into the right hip and back of the thigh. There had been a gonorrheal infection fourteen years before and an uncomplicated cure effected. He had slight nocturia.

The Wassermann reaction was negative, and examination of the urine and blood was normal. Röntgen ray examination of the teeth, spine and pelvis was negative. The tonsils had been cleanly removed. The prostate was enlarged 2, symmetric, slightly irregular in the right lobe, but not tender.

Examination of the prostatic secretion following provocative treatment revealed prostatitis 3. Seventeen treatments were given and the patient was greatly relieved.

CASE VIII.—A man, aged fifty-one, came to the clinic August 14, 1924, complaining of urticaria which had occurred at frequent intervals for nine years. The first attack followed a meal of sea food, starting with twitching sensations and dizziness. Attacks lasted for from eight hours to two or three days. Attacks finally became cyclic in character, occurring at weekly intervals. The patient had had gonorrheal infection in 1914; this had cleared up promptly and without complications.

The Wassermann reaction was negative. The urine contained albumin 2, casts and blood cells. The hemoglobin was 74 per cent., the erythrocytes numbered 4,370,000 and leucocytes 7,900. A fractional test meal revealed total acidity 80 and free hydrochloric acid 60. Röntgen ray examination of the teeth revealed a periapical lesion. Proctoscopic examination revealed internal hemorrhoids; the external genitalia were negative.

Examination of prostatic secretion revealed pus 4. The first examination was followed by a chill, rising temperature, and a typical urticarial rash. Slight reaction followed the second treatment. From August to September, 1924, seventeen treatments were given. There were no more attacks of urticaria after the second treatment. The patient's general health improved greatly and was excellent three months after dismissal.

CASE IX.—A man, aged thirty-five, came to the clinic June 27, 1924, complaining of trouble of the stomach and skin. He had had hematemesis, pyrosis, and pain one hour after meals for one year. He had no trouble on a vegetable diet. He had had a gonorrheal infection in 1906 and bilateral buboes and was treated with urethral injections. He had a second infection in 1921, followed in from two to three weeks by erythematous lesions on the back of the hands. Recently the feet, knees, and back had been affected. Diagnosis of erythema multiforme had been made. The lesions became vesicular after a few days of erythema, and following a gonococcal vaccine they disappeared to recur within a few weeks.

The Wassermann reaction and examination of the urine and blood were negative. The fractional test meal showed total acidity 40 and free hydrochloric acid 22. Röntgen ray examination of the stomach was negative. The tonsils had been cleanly removed. The provocative test for syphilis was negative. The prostate was small, smooth, regular and symmetrical.

Examination of the prostatic secretions July 8th revealed an occasional pus cell; July 12th, from twelve to fifteen pus cells.

Lesions receded rapidly after the first massage, Kollman dilatation and treatment with silver salt. They had entirely disappeared at the end of two weeks of treatment. The patient felt better than for years.

Case X.—A man, aged forty-four, came to the clinic July 12, 1924, complaining of fever, pain in the back and weakness of five weeks' duration. He had not felt well for several months. The pain radiated to the pubic region, was at times sharp, but never severe. It was associated with dysuria; there were aching sensations throughout the body, and headaches. Ten pounds in weight had been lost in the five weeks. Fever had been constant. He denied gonorrheal infection.

The Wassermann reaction was negative and examination of the urine was normal except for an occasional blood cell. The hemoglobin was 74 per cent.; the leucocytes numbered 7,200. The Widal test and blood culture were negative. The phenolsulphonephthalein return was 80 per cent. The temperature on admission was 101.8°, on the second day 100.6°, and on the third day 104°. Röntgen ray examination of the teeth, chest, kidneys, ureter and bladder was negative. The prostate was enlarged 2, symmetric, soft and nonsensitive. The vesicles were negative.

The first examination of prostatic secretion revealed 400 to 500 pus cells. Following the first expression of the secretion the temperature dropped to normal and remained so. Symptoms were greatly improved after a few treatments. The patient went home for further treatment.

Case XI.—A man, aged thirty, came to the clinic June 19, 1923, complaining of rheumatism in all the joints, chiefly the hands and feet. Seven years before, he had had gonorrhea and in a few days pain and swelling of the hands and feet. Following irrigation with permanganate of potash all general and local symptoms cleared up. The patient remained well for four years; the symptoms then recurred and during the last few months progressed rapidly. During the last three years the patient had been confined to bed frequently and had been unable to walk for four weeks. Muscular atrophy and general emaciation were marked.

The Wassermann reaction was negative. The urine contained albumin 1 and pus cells 3. The hemoglobin was 60 per cent., erythrocytes numbered 3,930,000 and the leucocytes 9,000. The tonsils were small and probably negative. Röntgen ray examination of the teeth was negative. The ray revealed destructive arthritis of the carpal bones of the right hand, ankle and foot, and calcaneal spurs. The prostate was enlarged, firm, regular and symmetric. The vesicles were slightly sensitive, but not infiltrated.

From June 25th to July 12th, eight treatments were given; from July 12th to August 25th, seventeen treatments; from August 25th to September 10th, seven treatments; from September 10th to January 1, 1924, fifty treatments; and from January, 1924, to November, fifty treatments. During this time two courses of aolan, a total of forty muscular injections, were given. August 3, 1923, seventy-five to 100 pus cells were found in the prostatic secretion; June 28, 1924, fifty pus cells; August 12th, 150 to 200 pus cells; and October 29th, twelve to fifteen pus cells. Findings have been negative since October, 1924.

July 12, 1923, the patient was in a wheel chair, feeling much better, gaining in weight and enjoying a good appetite. The rheumatism had greatly improved (60 per cent.). August 25th the patient was on crutches, was stronger and had much less pain. September 10th he was walking with a cane and by January, 1924, he was erect without a cane and practically free from pain. In April, 1924, he felt well and had only an occasional slight pain in the ankles. He was working steadily in November, 1924.

Case XII.—A man, aged forty-six, came to the clinic June 9, 1923, because of rheumatism of the hips and knees which began twenty-five years before, following gonorrheal infection. A second infection had occurred in 1911 with recurrence of rheumatic symptoms which gradually increased. Involvement of the cervical spine was noticed recently. During the last year the patient had had pain in the right eye, and blurring. He had slight nocturia.

The Wassermann reaction was negative. The hemoglobin was 76 per cent., the erythrocytes numbered 4,180,000, and leucocytes 7,100. The tonsils were slightly enlarged. Röntgen ray examination of the teeth revealed one periapical lesion; the spine was negative. There was hypertrophic arthritis of the left knee. The prostate was enlarged 1.

June 13, 1923, examination of the prostatic secretion did not reveal pus cells. June 18th, from eight to ten pus cells were found. Following ten treatments the vision became clear. The arthritis responded only slightly to treatment.

Case XIII.—A man, aged thirty-six, came to the clinic October 19, 1923, complaining of failing vision. Six years before, he had noticed a slight speck in the right eye, and later small floating opacities in both eyes. The condition had grown progressively worse. Gonorrheal infection was denied.

The Wassermann reaction was negative. The urine was normal except for pus 1 (seven cells). Hemoglobin was 75 per cent.; leucocytes numbered 11,700. Röntgen ray examinations of the teeth and chest were negative. The tonsils had been cleanly removed. The external genitalia, prostate, urethra and vesicles were normal.

October 14, 1923, prostatic secretion contained an occasional pus cell; on October 26th, twenty to forty pus cells, with small clusters; on November 9th, thirty pus cells; November 24th, five to eight; December 4th, 150, and December 14th, from eight to fifteen.

The general response to treatment was gradual, with gradual improvement in vision. Twenty treatments were given.

Case XIV.—A man, aged fifty-two, came to the clinic September 19, 1924, complaining of pain in the feet. He had had gonorrheal infection fourteen years before. Two and one half years before admission pain had developed in the bottom of the right foot which was worse on bearing weight. One year later a similar condition appeared in the left foot. The pain was increased with prolonged walking and was relieved by rest and elevation. More recently

numbness had developed and a dark, bluish discoloration appeared. The calves of the legs became painful. The patient became weak generally and lost weight.

The Wassermann reactions on the blood and spinal fluid were negative. The urine was normal except for an occasional pus cell. The hemoglobin was 82 per cent.; the erythrocytes numbered 4,840,000 and the leucocytes 7,200. Röntgen ray examinations of the teeth and left foot were negative. The tonsils had been removed, leaving tags on both sides. The prostate was slightly enlarged, indurated and irregular. The vesicles were distended but not infiltrated.

Examination of the prostatic secretion September 24th revealed seven pus cells and an occasional small clump. September 25th, an occasional pus cell was found; September 26th, 150 to 200 pus cells; November 23rd, twelve to fifteen with an occasional small clump.

October 28th the pain in the feet had greatly improved. A total of eleven treatments was given. The end results are indeterminate.

Case XV.—A man, aged thirty-seven, came to the clinic November 24, 1924, complaining of generalized pain, worse in the fingers and feet. He had had gonorrheal infection eight years before. Slight pains had occurred throughout various parts of the body for several years; these became marked about a year before admission, and were associated with numbness in the hands and feet. A cane was used because of weakness.

The Wassermann reaction on the blood and spinal fluid was negative. Urine was normal except for a trace of sugar. The blood was normal. Röntgen ray examinations of the teeth and stomach were negative. The tonsils were enlarged, soft, buried and contained a few plugs. The prostate was enlarged 2, firm, irregular and symmetric.

From 150 to 200 pus cells were found in the prostatic secretion. Indefinite improvement followed a course of ten treatments.

A Case of Bilateral Gynecomastia*

F. Y. DURRANCE, M.D.

New Orleans

This case is reported because it is unusual to find the condition occurring bilaterally with both mammæ lactating, in an apparently healthy young male.

Case.—A. S., male seventeen years of age, an Italian laborer, entered the medical clinic, Charity Hospital, New Orleans, La., March 8, 1925, complaining of enlarged and discharging breasts. He gave a history that the enlargement of the breasts was first noticed at the age of fourteen, and a year later he noticed that they were much larger than those of other boys of his age. They were at times slightly painful to pressure. Some time after this he noticed that on pressure of the nipples a whitish fluid would be expressed. Both breasts had been slightly tender from time to time since, and the secretion could be easily expressed from the nipples.

The family history was negative and there was no history of any member of the family having enlarged breasts.

Physical examination revealed a fairly well developed and well nourished youth of seventeen years, weighing 121 pounds, and 68 inches in height. The voice appeared normal for a youth of this age. The face was void of a masculine growth of hair except for a slight growth of extremely fine hair on the upper lip. There was no broadening of the hips, widening of the pubic angle or tapering of the hands. There was slight feminine distribution of the pubic hair.

Both mammæ were similar in appearance to that of a girl at the age of puberty. Each mamma measured five cm. in diameter, three cm. in height and had an areola of two cm. in diameter. There was a well formed nipple, which was distinctly erectile, on each mamma. Head, chest, abdomen and extremities were normal. Genitals were well developed; no

*From the Department of Medicine, Tulane University School of Medicine, New Orleans.

abnormalities detected. Wassermann negative; blood picture normal; urine negative. The breast secretion showed a white colored fluid of slightly less consistency than milk, containing a few epithelial cells, a few leucocytes, and a large number of fat globules.

Gynecomastia is a condition of hypertrophy of the male breast which causes it to assume more or less the size, appearance and in some ways the functions of the female breast. This condition may be either unilateral or bilateral and presents two factors for consideration—enlargement and secretion. The major portion of the literature on the subject considers only the enlargement, while we do find cases reported infrequently which tell of the secretory or lactating ability of the gynecomastia. It is of marked interest to note the infrequence with which the secretory activities occur. The condition presents further points of interest in that the cases which occur early in life or before puberty seem to show a tendency to a lack of development of the external genitalia or of the sexual organs; while those occurring about the time of puberty on the whole show no abnormalities of the sexual organs; and yet those occurring in later life are associated to a large extent with sexual defects, which in the majority of cases are due to the results of injury or disease. From a sex viewpoint, two types may be considered; in the one the condition is associated with a normal sexual function, while in the other testicular defects are always present.

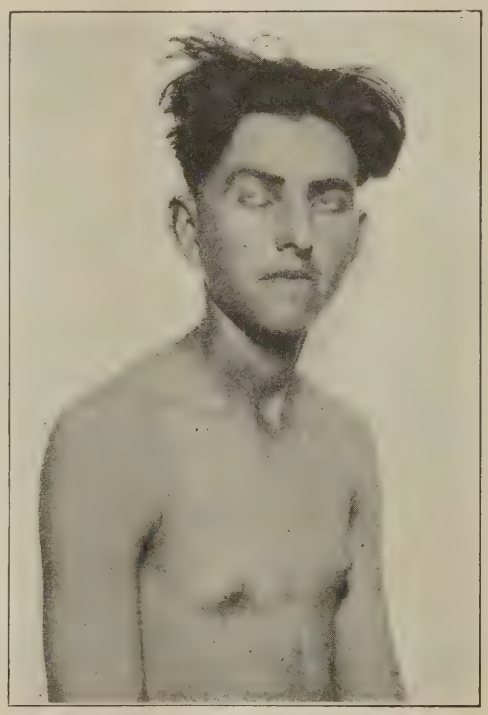

FIG. 1.—Female characteristics of the breast in a young male.

In a study of the reported cases and the writings on the subject of gynecomastia, it is noticed that the condition was much more common in earlier times than at present, and was of much greater frequence among the lower races of human beings than it was among those of higher development, and a fairly high percentage is reported among the criminal classes and inmates of institutions of reform.

Certain theories of gynecomastia are given, as: Atavistic phenomenon, supported by the facts that lower races have larger mammary glands than those of higher races and that the condition seems to be normal among the Abyssinian and Galla youths and is also quite common among the tribes of the Sudanese; sign of degeneration, which we may consider a modification of the former theory; sign of sexual abnormality, since it occurs in association with imperfect development of the sexual organs, also in pseudohermaphroditism, and may result from diseases or removal of the testes; local traumatic injury, where a few cases have developed following trauma of the breast.

From the viewpoint of gynecomastia being a hereditary condition, there are several reported cases where there are father and son who are gynecomasts, and others showing several gynecomasts in the same family. Yet, since it is suggested that the condition is the result of disturbances of internal secretion, it may be possible that certain families are peculiarly susceptible to certain endocrine dystrophies, which may account for the occasional familial occurrence of the condition. There are a number of cases to which no cause for the condition can be assigned, that is, cases where there is no known inherited tendency, no sign of degeneration, no sexual disturbance and no history of local injury to the part.

It may be said that the condition is frequently unilateral, though more often bilateral. The age incidence is undetermined, though the greater number of cases are reported from the age of puberty to adolescence. The general appearance of the breasts is usually described as being like the virginal mammæ of a girl of fifteen to sixteen years of age. The enlarged breast is infrequently attended by pains which vary from a dull aching to severe lancinating or burning sensations. The tendency of the enlargement is to persist and secretory activities sometimes do occur.

The size, general appearance, female type and tactile sensation of the breasts are usually sufficient evidence to permit the diagnosis. The prognosis is good; the patient can expect no change in the enlarged breast, and there is little or no danger of future complications. Only a few cases require treatment. The condition is an anatomico-physiological anomaly rather than a disease, and the only treatment to be recommended is amputation or plastic resection.

It is interesting to note that in 162 cases of gynecomastia tabulated by Deaver and McFarland, there were sixteen subjects showing secretory activities, and twenty having normal sexual organs, and of the twenty with normal sexual organs the ages were from twelve to twenty-three years.

Diathermy in Pelvic Infections*

THOMAS H. CHERRY, M.D., F.A.C.S.
New York

Diathermy can be defined as the penetration of tissue with an electrical current of high frequency that results in heat production. This thermic result develops within the tissues and at any depth when the D'Arsonval current traverses between two electrodes.

The amount of heat generated depends, first, upon the number of milliamperes utilized; second, the size of the electrodes; third, the resistance of the tissues; fourth, the length of time the current is applied.

By the use of this electric agent any degree of heat can be manufactured in the human tissues from 37.5° C. to 60° C. When heat is generated from 37.5° C. to 52° C. for therapeutic purposes it is called medical diathermy; when a greater degree of heat is produced tissue destruction begins and at 60° C. is completed. The latter procedure is named surgical diathermy, or electrocoagulation.

Medical diathermy can be applied to any tissue and at any depth, provided the part treated lies between two electrodes. The current of electricity travels the shortest distance between the two electrodes, thus generating heat. When the electrodes are of the same size the heat produced in the tissues is greatest at a point midway between them. When electrodes of different sizes are used the greatest point of heat generated is nearer the small one. These principles are readily utilized in applying the maximum point of heat to different pathological sites by varying the size of the electrodes.

In surgical diathermy, or electrocoagulation, when destruction of tissue is desirable, one large surface electrode and a small active electrode are always used. This gives a maximum amount of heat at the point of contact of the smaller electrode, which, with sufficient amount of current, produces a temperature up to 60° C. with consequent destruction.

The action of heat upon diseased structures is well known. An active hyperemia is brought about, the intensity of which depends upon the degree of heat and the length of time administered. As a part of the hyperemic process a quickening of the circulation occurs and accompanying this there is a dilatation of the capillaries that allows the fluid elements of the blood to transude into the tissue spaces. When this action takes place in the presence of inflammation there is a reduction of the stasis in the engorged bloodvessels and relief of pressure upon the nerve filaments, thereby decreasing pain. There is also a greater and quicker absorption of the exudate, for by the increased flow of blood to the pathological site more units of Nature's defense against invasion are mobilized.

The bactericidal action of heat is an important feature to be considered in diathermic applications. Heat destroys different bacteria at different degrees of temperature. Some are killed at lower degrees than others. The gonococcus is destroyed by an exposure to 41° to 43° C. for ten minutes. It is for this reason that the application of diathermy has met with the success it has in pelvic infections.

TABLE 1

DEGREE OF TEMPERATURE DESTROYING DIFFERENT PYOGENIC BACTERIA

Bacteria	*Temperature*
Gonococcus	41°-42° C.
Streptococcus	54°-60°
Staphylococcus	56°-58°
Pneumococcus	52°
Tubercle bacilli	60°
Colon bacillus	60°

In the gynecological service of Harlem Hospital we consider eighty-eight per cent. of the patients suffering from adnexal inflammation to have the gonococcus as the inciting factor of their disability. During the last three months fifty-two patients having pelvic infections were treated with diathermy. Thirty-six patients had definite masses in one or both adnexa. All were admitted seeking relief from abdominopelvic pain and everyone had an endocervicitis; some had a urethritis.

TABLE II

PATHOLOGICAL CONDITIONS TREATED WITH DIATHERMY
TOTAL NUMBER OF CASES—FIFTY-TWO

Pathological Condition.	*Number*
Adnexal disease, with masses	36
Adnexal disease, without masses	14
Puerperal infection	2
Endocervicitis	48
Urethritis	26
Skene's glands	6

ADNEXAL DISEASE WITH MASSES

Eighty-eight diathermy treatments were given to this group. The lowest number of treatments given was one and the highest number was nine, to a single individual. The masses in twelve patients disappeared; in ten patients the masses were perceptibly reduced in size; in fourteen patients there was no reduction of the masses. The pain for which they sought relief was practically relieved in all cases by the first application. Two patients had recurrence of pain but were relieved by subsequent treatments. No other treatment was instituted, nor were there any analgesics administered for the control of pain. The best results in this group were obtained among those patients who had the highest number of treatments for longer periods of time (twenty-five to thirty minutes), and when the vaginal temperature was maintained at 43° to 47° C. From this group six patients were operated upon who continued to have pelvic masses and discomfort.

TABLE III

ADNEXAL DISEASES WITH MASSES
TOTAL THIRTY-SIX CASES—DIATHERMY TREATMENTS, EIGHTY-EIGHT

Application	*Number of Treatments*	*MA.*	*Minutes*
Sacroabdominal	33	1500-4000	15-30
Abdominovaginal	55	1500-2500	15-25

Raising of vaginal temperature 43°-45° C.

*From the Gynecological Division of Harlem Hospital.

RESULTS

	Number of Patients	Per Cent.
Relief of pain	36	100
Recurrence of pain	2	...
Disappearance of masses	12	61
Reduction of masses	10	

PATIENTS RECEIVING FIVE OR MORE TREATMENTS

TOTAL TEN CASES

	Number of Patients	Per Cent.
Masses and tenderness entirely disappeared	8	80
Masses and tenderness were markedly reduced	2	20

ADNEXAL DISEASE WITHOUT MASSES

A group of fourteen patients had no masses but the adnexa were thickened and tender and they had the usual endocervicitis: some had urethritis and Skene's gland involvment, which stamped them as gonorrheal in origin. Of this group twelve patients were relieved of their pain: one patient did not get relief. In all, only fifteen treatments were administered averaging one to each patient.

TABLE IV

Adnexal Diseases Without Masses

TOTAL FOURTEEN CASES

DIATHERMY TREATMENTS—FIFTEEN

Application	Number of Treatments	MA.
Sacroabdominal	9	1500-4000
Abdominovaginal	6	1500-2500

Raising Vaginal Temperature 43°-45° C.

RESULTS

	Number P.
Relief of pain occurred in	13
No relief of pain occurred in	1

ENDOCERVICITIS GROUP

Forty-eight patients had endocervicitis with an accompanying thick, heavy, tenacious, mucopurulent secretion. Thirty-nine endocervical treatments were made with the thermophore; however, there were fifty-five applications made with the vaginal electrode for the accompanying adnexal infection that no doubt produced a rise of temperature in the cervical tissues. In this group twenty-four were cured or showed a marked diminution of the amount and the character of the discharge which had changed to a thinner and less purulent material. Twenty-four patients showed no improvement.

TABLE V

Endocervicitis Group

OCCURRING WITH ADNEXAL DISEASE OF GONORRHEAL ORIGIN

TOTAL FORTY-EIGHT CASES

Aplication	Diathermy Treatments	MA.	Minutes
Abdominocervical	39	500-800	15-30

Temperature of cervical canal maintained 43°-47° C.

RESULTS I

	Number
Patients receiving two or more treatments	9
Patients cured or markedly improved	6

RESULTS II

	Number
Patients receiving one treatment each	18
Patients cured	2
Patients improved	10
Patients unimproved	6

URETHRITIS GROUP

There were twenty-six patients who had urethritis; of this group only thirteen were treated with twenty-one applications of diathermy by the Corbus thermophore. They were given 600-800 milliamperes until the thermometer registered 43°-47° for twenty to thirty minutes. Six patients were cured of the discharge, and six were improved; one patient showed no improvement.

Cured	6
Improved	6
Not improved	6

There were seven patients, however, who had two or more treatments; five of these were cured, and one was much improved. This latter group, although very small in numbers, however shows the efficacy of more treatments than the average patient received suffering from this condition.

TABLE VII

PATIENTS OF THIS GROUP HAVING TWO TO THREE TREATMENTS

TOTAL SEVEN CASES

RESULTS

	Number
Cured	5
Much improved	1
Not improved	1

In spite of the infrequency and few number of urethral treatments received forty-six per cent. were cured and forty per cent. improved.

Of the patients who had infections of Skene's glands, diathermy application was made to the urethra with the thermophore, treating them as the urethritis group cited. There were six such cases, of which five were cured; one patient persisted with a mucous discharge from the right gland and it was necessary to apply coagulation in order to effect a cure.

Of the six patients operated upon who had persistent masses following diathermy treatments the pathological findings were pyosalpinx and tubo-ovarian abscesses. All six patients had the diathermy treatments administered by the abdominovaginal and abdominosacral application of electrodes. Three patients had three treatments each; one had four treatments; one had five treatments, and one had seven treatments. The amount of milliamperes used in the abdominovaginal application was 1500-3000; in the abdominosacral application 2500-4000 milliamperes was employed. In every instance sufficient current was utilized so as to elevate the temperature in the vagina to 43° to 47° C.

The following gross appearance at operation may be of interest: First, the adhesions instead of the usual hard fibrous bands between intestines and pelvic structures were thinner, more vascular, and, in consequence, more easily separated. Second, the inflammatory masses, themselves, seemed softer and more succulent, rendering their delivery into the abdominal wound more readily accomplished. Third, the contents of the masses consisted of a thin, watery exudate instead of the purulent material usually encountered. Cultures of the fluid, as well as tissue cultures, were done in three cases showing no growth.

One also was impressed by the smooth postoperative course of these cases—the comparative freedom from pain, distention and vomiting of the patients, and wounds free from infection.

Two postpartum adnexal infections were each given one application of diathermy with disastrous results in one case and the institution of an acute pelvic peritonitis in the other case, that resulted in a pelvic abscess, requiring evacuation of the pus through the vagina. This type of infection is not suited for diathermy treatment as the degree of heat necessary to be generated to destroy the activity of the streptococcus, staphylococcus or Bacillus coli cannot be utilized without destroying other tissue. A lower degree of heat probably serves in revivifying bacteria that are dormant, thus bringing about a more suitable cultural environment, thereby inciting a fresh infection.

CONCLUSIONS

From observations based upon the patients treated for pelvic infections at Harlem Hospital with diathermy the following conclusions have been reached:

1. In pelvic infections of gonorrheal origin it is the treatment of choice.
2. It relieves abdominopelvic pain almost instantly.
3. It causes the disappearance or reduction of the pelvic masses in sixty-one per cent. of instances.
4. It cures or diminishes the endocervicitis in ninety per cent. of cases, thus preventing a reinfection of the adnexa from the cervical canal.
5. As a preliminary treatment to operation among patients whose pelvic masses persist, it is the best agent we possess, for if sufficient treatments are administered the pus contents of the tubes are rendered sterile and innocuous. In consequence a more rapid and successful convalescence ensues.
6. In urethritis and Skene's gland infections it is the treatment of choice.
7. The employment of diathermy in postpartum or postabortion infections cannot be recommended, as the degree of heat generated in the pelvis is insufficient to devitalize the type of bacteria producing the infection.

Digestive Symptoms Caused by Disease of the Abdominal Vessels

*With Special Reference to Arteriosclerosis**

I. W. HELD, M.D.
New York

(*Concluded from page 10*)

The symptoms may sometimes be so severe as to simulate a ruptured gastric ulcer, hemorrhagic pancreatitis or ruptured gallbladder. The differential diagnosis is difficult and often impossible. It may be said of angina abdominalis that it is brought on as in angina pectoris by exertion or after a heavy meal. The symptoms are usually of a transient nature. In some cases the repeated attacks and the fact that the patient is relieved by vasodilators, such as diuretin or nitroglycerin, will help in establishing the proper diagnosis.

In a great number of cases the symptoms are due to spasm of the intestinal vessels either in the angioneurotic or angiosclerotic stage. This symptom complex was first correctly interpreted by Schnitzler who called it intermittent anemic disperistalsis of the intestines. Soon after E. Neusser described some cases. Ortner, who gave the best description of the symptom complex, termed the disease dyspragia intermittent angiosclerotica intestinalis. In this country Gilbride, W. W. Hamburger, G. A. Friedman, and recently Jacob Meyer made valuable contributions to the subject.

The symptoms are at first of a transient nature and consist of fullness and a feeling of tension in the abdomen and progressive constipation with a sensation of having the desire to go to stool but without success. Loss of appetite, belching, nausea and anxiety may also be present.

In the vast majority of cases the symptom complex is as follows: The abdominal pain is the most striking symptom. It occurs periodically and is diffuse over the entire abdomen and may be of a lancinating penetrating character, reaching its maximum intensity within one half to one minute and lasting from ten to fifteen minutes and sometimes for several hours. In rare cases the pain lasts several days to a week. The severity of the symptoms varies during different attacks. The pains may sometimes be so severe as to cause the sensation of impending death or give rise to fainting. The fainting spells are more outspoken if the pain is confined to the upper abdomen. Repeated attacks may occur during the day. In other cases the patient may be free from attacks for weeks or months. The patient usually attributes the attacks to exertion, psychical trauma or heavy meals, especially such that cause abdominal distention. In some cases the pain may wake the patient from sleep. Some patients cannot lie flat on their backs and are compelled to sleep in a semirecumbent position. In most cases the abdomen is distended and meteorism is marked. The diaphragm is pushed up to such an extent that it causes dyspnea, palpitation, and increased pulse rate.

Meteorism may be as marked as in peritonitis, but unlike the latter, intestinal sounds can be detected on auscultation. When borborygmi sets in, the patient usually is relieved. Vomiting occurs but it is not the rule. The meteorism usually affects the cecum and transverse colon. In the case reported by Jacob Meyer the distention of the transverse colon was so marked as to fill the entire abdomen. In some of the cases it is associated with thromboangiitis

*Read before the Eastern Medical Society, November 14, 1924.

obliterans. Jacob Meyer speaks of the condition as thromboangiitis obliterans of the abdominal vessels. His case and the one reported by G. A. Friedman were associated with thromboangiitis obliterans of the lower extremities. The author saw two cases associated with thromboangiitis obliterans.

The diagnosis of dyspragia intestinalis is very difficult because a number of other intraabdominal conditions may give rise to similar symptoms as, for instance, cholecystitis, appendicitis, nephrolithiasis, intestinal obstruction, hemorrhagic pancreatitis, twisted ovarian pedicle, lead colic, tabetic crisis, or nicotine abuse. In the presence of thromboangiitis obliterans of the lower extremities or general arteriosclerosis, the diagnosis may be possible. The diagnosis is also facilitated if there is considerable freedom of symptoms between one attack and the other. The prognosis in these cases depends on whether the symptoms are angioneurotic or angiosclerotic in nature. If the symptoms are due to an angioneurosis, the patient may, after repeated attacks, become free from symptoms and remain so for the rest of his life. In the angiosclerotic stage, there is a tendency for the symptoms to recur and become more marked.

In discussing the abdominal symptoms due to disease of the abdominal vessels, those caused by thrombosis of the mesenteric vessels must be mentioned.

The distribution of the mesenteric vessels to the abdominal organ is as follows: the superior mesenteric artery supplies through the inferior pancreatic duodenal artery, the duodenum; through the jejunal and iliac arteries, the jejunum and ileum; through the ileocolic artery, the lower ileum and cecum; through the right colic artery, the ascending colon; and through the middle colic artery, the right half of the transverse colon. The inferior mesenteric artery supplies the distal half of the transverse colon. The left colic artery supplies the sigmoid through the sigmoid artery. The upper rectum is supplied by the hemorrhoidal vessels. The superior mesenteric vein corresponds in its distribution to the mesenteric artery. The inferior mesenteric vein and the superior hemorrhoidal veins form a rich anastomosing network in the hemorrhoidal plexus with the hypogastric veins. Both veins form, with the veins supplying the stomach and the spleen, the main branches of the portal vein.

Although the mesenteric arteries are not terminal vessels the collateral circulation, under pathological conditions, is insufficient for the proper functioning of the intestines. This is the reason why Litten terms the superior mesenteric artery "functional terminal artery."

Obliteration of the mesenteric vessels is a rare disease. Embolism of the mesenteric artery is more frequent than thrombosis. The superior mesenteric artery is more frequently affected than the inferior. Emboli of the mesenteric arteries are usually carried from the heart or aorta, more rarely from the pulmonary artery. It is encountered in the course of infectious polyarticular disease, septic endocarditis, chronic valvular disease, chronic myocarditis, aortitis, aneurysm of the aorta, and ulcerated sclerosis of the superior mesenteric artery proper.

Thrombosis of the mesenteric artery usually results from arteriosclerosis, especially if of luetic nature. The occlusion may be caused by endarteritis obliterans or by wall thrombi. The sclerotic thrombi of the mesenteric arteries lead to infarction of the intestines and to gangrene. Thrombosis of the mesenteric veins is mostly the consequence of inflammatory changes in the abdominal organs, especially the intestines. It occurs frequently in the course of septic thrombosis during appendicitis and after infectious enteritis. Septic and aseptic venous mesenteric thrombi may be the result of intestinal strangulation or invagination or may follow gastroenterostomy or splenectomy. The condition is also at times encountered in syphilis, typhoid, general carcinomatosis, dysenteric ulceration of the intestines, suppurative parotitis, carbuncles of the neck, operations on the thyroid and after delivery.

Secondary mesenteric vein thrombosis may follow primary thrombosis of the portal vein.

Thrombosis of the mesenteric arteries and less frequently of the mesenteric veins may occur in the course of infectious polyarterial thrombosis. Eichhorst considered the condition to be due to the infection involving first the adventitia and from there spreading to the media and intima. In the two cases described by Eichhorst the thrombi were found in multiple vessels (femoral, iliac, renal and mesenteric) without any lesion in the valves of the heart. One of his cases occurred in the course of scarlet fever. He, therefore, attributed it to an infection of the bloodvessels proper. A similar case was recently described by Hampeln.

SYMPTOMS

Litten's experimental work, as well as his clinical observations, show that shortly after the mesenteric vessel is obliterated there is an increased excitability of the motor nerves and the muscles of the intestines leading to increased intestinal peristalsis which is responsible for the diarrhea. At times the increased excitability of the intestines causes spastic contraction of the colon with obstinate constipation. As a rule, however, there is diarrhea associated with severe pains and vomiting.

The onset is usually sudden whether the thrombosis affects the artery or the vein. The patient complains of severe colicky pains and nausea. Violent peristaltic contractions of the affected anemic part of the bowel is usually present. Singultus and vomiting are early symptoms. Vomiting is rarely fecal. Hematemesis is also very rare, but if present it is due to the blood regurgitated from the intestines into the stomach. Bloody stool is more frequent and according to most statistics it is encountered in fifty per cent. of the cases. Another very striking symptom is collapse. The pulse is rapid, the temperature subnormal, the face pinched, and the extremities are cold.

The first symptoms resemble greatly those of intestinal obstruction due to strangulation. However, in contradistinction to strangulation, thin, bloody bright red or dark red stool is present in mesenteric thrombosis. The loss of blood may be considerable and in part responsible for the fatal termination. In a small number of cases death occurs during the stage of shock before the symptoms of intestinal occlusion set in. The initial symptoms of collapse last from about twelve to twenty-four hours after

which the signs of intestinal occlusion make their appearance and they remain throughout the course of the disease. Very often the pains are so severe that the patient moans continuously to the end of his life. At times visible peristalsis may be noticed over that part of the colon which is obstructed. Death usually results within the first week. Very seldom recovery takes place. It may be stated that the longer the disease lasts and the milder the symptoms the better are the chances for the reestablishment of the collateral blood supply.

Thrombosis of the abdominal aorta or vena cava inferior is usually the consequence of disease of the bloodvessels proper. Thrombosis of the abdominal aorta is due to arteriosclerosis; thrombosis of the vena cava inferior is often due to syphilis.

Thrombosis of the portal vein plays an important rôle clinically. It may occur in the course of cirrhosis or syphilis of the liver or be due to sclerotic changes in the wall of the portal vein. The thrombosis may run a chronic course. It may also be due to thrombosis of the mesenteric veins. At times pressure from without by cancer of the neighboring organ, enlarged lymphatic glands, gallstones and more rarely trauma may cause thrombosis of the portal vein.

Acute occlusion of the portal vein causes profuse gastrointestinal hemorrhages with resulting death. If thrombosis develops gradually, ascites is present, spleen and liver become enlarged and there is frequently icterus. In case of primary thrombosis of the portal vein without any other disease, collateral circulation either through the vena cava superior and inferior or through the hemorrhoidal vessels may take place causing a disappearance of the symptoms.

Another vascular symptom complex of the gastrointestinal tract not caused by inherent disease of the gastrointestinal vessels must be mentioned here, namely, the socalled angioneurotic edema described by Quincke and soon after by Osler. That angioneurotic edema of the skin is very frequently associated with gastrointestinal symptoms is a well known fact. According to Collins, the skin manifestations are accompanied by acute transient edema of the gastrointestinal tract in about thirty-four per cent. of the cases. In the milder cases the pains in the region of the stomach are more or less intense but they disappear rapidly. In more severe cases the pain may become so intense that Rapin termed it abdominal migraine. There is frequently associated nausea and vomiting. The vomiting consists of pure gastric secretions sometimes mixed with bright red blood. At times the clinical picture simulates gastric crises.

In other cases, the intestinal symptoms predominate. The pain is colicky in nature confined to the lower abdomen, accompanied by marked abdominal distention and obstinate constipation. The pain may localize itself in the ileocecal region giving rise to symptoms of appendicitis or in the sigmoid region simulating sigmoiditis. In either case the diagnosis is soon cleared by the presence of bloody stools. The differential diagnosis between sigmoiditis and angioneurotic edema of the intestines may be determined by the fact that in sigmoiditis there is a tendency to diarrhea, the bloody stools are more profuse and the duration of the disease is much longer. In cases where diarrhea is a marked symptom there is excessive thirst, diminution in the urinary output and marked exhaustion. Cases are reported where the colicky pains are of such severity as to simulate a surgical disease and lead to unnecessary laparotomy. The temperature is often normal but may be moderately elevated. Some cases have been reported where high temperature was present for a few days. Where the gastrointestinal symptoms are preceded or accompanied by skin manifestations in the form of urticaria or angioneurotic edema, the diagnosis is simple. Cases, however, are encountered where the gastrointestinal symptoms set in a few days before the skin manifestations or where there are no skin manifestations at all, making the diagnosis very difficult or impossible.

The symptoms have a great tendency to recur. They usually affect several members of the same family but not necessarily during the same time. The familial relationship is as a rule characterized by the fact that not all the members get gastrointestinal symptoms at the same time. One member may get only skin and another one only gastrointestinal manifestations. I know a woman who suffers from time to time with angioneurotic edema. One attack was accompanied by edema of the glottis which cleared up very quickly by adrenalin. One of her children suffers from attacks of asthma and angioneurotic nasal manifestations and another child from gastrointestinal symptoms.

The pathogenesis of the disease is not definitely established. The studies of Cook, Walker, Rolleston, Widal and others, show that this affection is probably due to protein sensitization. The hypersensitiveness to the proteins is as a rule acquired during life. The hypersensitiveness which is at first latent becomes manifest by protein intoxication. Very often the hypersensitiveness is not due to a single but to a number of proteins. Numerous experiments have been performed to prove that protein sensitization is a great factor in this disease. Of the many experiments recorded the one of Phillips is the most striking. Phillips fed a five months' old bulldog for the first time the protein of pork and this was immediately followed by vomiting, bloody diarrhea and edema of the skin. The symptoms lasted forty-eight hours. One year later this dog showed definite skin reaction when protein of pork was rubbed into the skin. Another dog suffered from the same symptoms when preserved fish was fed to him.

It may, therefore, be assumed that in the majority of cases of angioneurotic edema, there is an individual predisposition where the lymphatic apparatus irritated by certain proteins causes an increased secretion of lymph or increased permeability of the small lymph vessels bringing about edema of the tissue supplied by these vessels. In the majority of cases the hypersensitiveness manifests itself by the oral administration of the respective proteins. In rarer cases the subcutaneous injection may bring about the symptoms.

Although there is no doubt that the exciting cause is the hypersensitiveness to certain proteins, it cannot be denied that the inherited constitutional neuropathic element is an important factor. This explains why psychical influences and excessive mental strain so frequently bring on the symptoms. Bolton demon-

strated experimentally that angioneurotic edema is the consequence of sympathicotonia. His work, however, is by no means conclusive.

Prophylaxis may be a great factor in individuals whose predisposition to vascular changes is marked. It is unfortunate that the social conditions of the patient play so great a rôle in the carrying out of such treatment. Prophylactic measures in the asthenic type should be carried out even during puberty through well regulated physical exercise thus training the circulatory system at large and the gastrointestinal tract in particular. An effort should be made during puberty to overcome constipation by proper diet and abdominal massage and not by laxatives and enemas. The diet should be nutritious, consisting of five small meals daily. Fluids should be restricted, especially with meals. A well fitted abdominal binder is beneficial. Hydrotherapy in the form of daily lukewarm baths and cold shower baths followed by friction should be resorted to.

In the plethoric individual, prophylaxis should be in the form of diet and exercise. Caloric intake should be limited in order to avoid overweight. If there is a tendency to overweight the following is suggested: a starvation day once in ten or twelve days consisting of green vegetables, some fruit and buttermilk. The loss of weight on such a starvation day may be two or three pounds. The patient should be ordered to keep within his diet so that the two or three pounds lost should not be regained within the next twelve or fourteen days. Following such a procedure the patient in the course of the year may lose twenty-five pounds or more, thus keeping at the desired weight. The encouragement of rapid loss of weight is harmful in individuals who have a tendency to circulatory weakness. In the plethoric type the hydrotherapeutic procedure may be more strenuous (warm baths, cabinet baths, general body massages, especially the abdomen). A patient will be greatly benefited by a month's visit to one of the spas.

If the symptoms indicate organic changes, such as erosion or ulcer of the stomach, appropriate treatment should be enforced. One should remember that in these individuals the organic symptoms are masked by the general nervous manifestations and we should not be misguided in treating these individuals as neuropaths which so often leads to disastrous results to the patient.

The severe abdominal pains in dyspragia intestinalis are very resistant to treatment. Morphine and atropine are indispensable in very severe attacks. Meteorism is a very troublesome symptom. This should be treated by colonic irrigations and turpentine stupes. Pituitrin is not useful in these cases. Suppositories of codeine sulphate one half grain and luminal two grains once or twice a day for a few days will relieve pains. Vomiting is also a troublesome symptom and frequently gastric lavage must be resorted to; it is not contraindicated unless the blood pressure is very high. The diet should be restricted (strained barley soup, tea with milk, yolk of eggs, vichy). The symptoms very often disappear abruptly as in tabetic crisis.

The severe attacks of abdominal angina may be combated with nitroglycerin and by prolonged use of diuretin and physical and mental rest. Dietetic régime should be managed according to arteriosclerosis. Such a patient should have complete rest one day each week. Absolute inactivity should never be enforced except in advanced cases. Proteins should be restricted to seventy to eighty grams a day and a minimum of sodium chloride should be allowed. It is often necessary to use for a longer time diuretin with some anodynes, such as pantopon one third grain or papaverine one third grain.

During the free interval cases of abdominal angina are favorably influenced by carbon dioxide baths which are to be taken only under proper supervision. If the blood pressure is increased after these baths, the treatment should be discontinued. Hemorrhages from the stomach or intestines do not as a rule necessitate very active treatment as they have a tendency to stop abruptly. In severe cases, however, if the hemorrhage does not cease upon the application of ice coil over the abdomen or the hypodermic use of morphine, the intravenous injection of ten c. c. of five per cent. calcium chloride, ten c. c. of hypertonic sodium chloride solution or intramuscular use of ten per cent. sodium citrate as advocated by Neuhof and Hirschfeld, may be resorted to. Hypodermoclysis in blood transfusions are seldom necessary in these cases. It need hardly be mentioned that individuals with outspoken evidence of arteriosclerosis should be guided in their physical and mental duties.

Treatment of mesenteric thrombosis is surgical. In most cases, however, the primary disease is of a fatal character and surgery is usually ineffectual.

The acute attack of angioneurotic edema is at times favorably influenced by the subcutaneous administration of ten drops (1-1,000) adrenalin solution every half to one hour for three or four doses. Two injections daily may be given the next three or four days. Internally, calcium may be administered either in the form of calcium lactate ten grains three times a day or what is more effectual five c. c. of five per cent. calcium chloride intravenously. One must be careful that not a drop escape under the skin, as the calcium chloride is very irritating and causes sloughing of the skin. In order to prevent recurrent attacks, desensitization tests carried out by one well trained in the interpretation of the results should be performed. The results of such examinations are often disappointing. It is also best to instruct the patient to be observant of his diet, in order that he may notice the articles of food which bring about the symptoms. It may be laid down as a rule that sea food and berries should be avoided. If the desensitization test demonstrates the foods that are the causative factors it is not absolutely necessary to exclude these articles of food. It may be best to follow the method advocated by Eskuchen which consists in allowing the patient small quantities, not exceeding one half to one gram, of food to which he proves sensitive and ten to fifteen minutes later more of the same food may be taken without any ill effects. It is to be understood that most subjects are neuropaths and often proper treatment by neurologists and psychoanalysts proves effectual.

SUMMARY

1. Attention is called to a group of gastrointestinal symptoms caused primarily by changes in the bloodvessels supplying the gastrointestinal tract.

2. The symptoms are caused by vascular changes of an angioneurotic or angiosclerotic nature. The

angioneurotic element predominates in cases occurring before middle age, whereas arteriosclerotic changes predominate after middle age.

3. In cases where the angioneurotic element predominates the symptoms are mainly of functional nature and hence such persons are wrongly interpreted as psychopaths.

4. Arteriosclerotic changes in the gastrointestinal vessels may be more marked than in the other vessels of the body. As a rule, however, the condition is associated with general arteriosclerosis. Gastrointestinal symptoms caused by angioneurosis occur far more frequently than is ordinarily appreciated.

5. Both angioneurosis and angiosclerosis are found most commonly in the two extreme types of subjects; the asthenic type and the apoplectic type. In the former the angioneurotic symptoms precede by many years the angiosclerotic symptoms, whereas in the latter type angiosclerosis is the cause of the symptoms.

6. During both the angioneurotic and the angiosclerotic state, pathological changes develop in those organs supplied by the affected vessels.

7. Angioneurosis of the gastric vessels may lead to gastric spasticity. This condition if persisting for longer periods of time may cause erosion and ulcer formation. Arteriosclerosis of the same vessels, interfering with the nutrition of the stomach, may likewise lead to gastric ulcer.

8. In cases where the gastrointestinal symptoms are marked, and general nutrition is disturbed, the symptoms may simulate malignancy.

9. The diagnosis is extremely difficult and can be made only in the presence of arteriosclerotic changes in other parts of the body and where organic disease of the gastrointestinal tract may be ruled out.

Transposition of All the Viscera*

JACOB M. CAHAN, M.D.
Philadelphia

While transposition of all the viscera is not an infrequent occurrence, it is most unusual to have two members of one family exhibiting this condition.

Aristotle (1) observed quadrupeds showing transposed liver and spleen. The first record of transposed viscera in human beings was made by Gemma (1) about the middle of the sixteenth century. Percussion and auscultation, as aids in recognizing the condition during life, were discussed in 1824 (2). Röntgen study of visceral transposition was made in 1897, and Nicolai (3) and Hoke (4), in 1911, described the earliest electrocardiographic curves in this condition.

A survey of the literature indicates that to date there have been reported or collected principally by Gruber (5), Küchenmeister (2), Arneill (5), Schelenz (1), and Sherk (6) over 270 cases of transposition of all the viscera. The condition is said to occur almost twice as frequently in men as it does in women (5). There is no record of its being observed in parent and child. There seems to be only one other instance of two cases in the same family (7). The underlying determining factor is not known. The consensus of opinion seems to trace the abnormality to an altered relation of the embryo to the primitive chorionic villi (8) at a very early stage of embryonic life. Willius (9) assumes that the "embryo lies in an abnormal position within the chorion, so that its right side instead of its left lies closer to the blood supply."

Uncomplicated transposition of all the viscera offers no symptoms, and has no clinical significance. The incidence of disease is the same as in normal individuals. It is interesting to note that most persons with transposed viscera develop a normal speech centre (in the left side of the brain), and are right handed. The normal clinical signs of the organs are clearly demonstrable on the opposite side of the body. Röntgen studies confirm the clinical findings. Electrocardiographic tracings show the pathognomonic sign of inversion of all waves of Lead 1, and the small excursions of waves of Lead 2.

The diagnosis of transposition of all the viscera depends upon a careful physical examination of the bared chest and abdomen. There is no pulsation, dullness or flatness over the precordium, or distinct sounds over the usual apical region. The heart sounds, if heard at all, seem distant. Upon shifting the stethoscope to the right mammary region, the condition is at once suspected. A visible systolic impulse, if not previously observed, in the right midclavicular line, cardiac dullness and apical sounds over the corresponding area on the right side clinch the diagnosis of dextrocardia. In addition, the apparent freedom from any grave constitutional disease, the absence of signs of any gross pathology in the chest that might possibly displace the heart to the right, and the presence of signs of lung tissue over the normal cardiac area make transposition of the heart quite evident. Attracted to the examination of the abdominal viscera one is surprised to find no dullness in the right hypochondrium, but, instead, distinct tympany, and, perhaps, peristaltic sounds below the heart dullness. The left hypochondrium, on the other hand, shows hepatic signs from the fifth rib down to the costal margin, or below it. There is no normal gastric tympany.

The differential diagnoses of thoracic and abdominal conditions are so greatly assisted by the positive signs of the transposed viscera that, having found these, the signs of possible pathological conflicting conditions in either body cavity need not be discussed. The additional evidences furnished by the fluoroscope, the x ray and the electrocardiogram are valuable records in corroborating the diagnosis. According to Lewis (10), "The electrocardiographic test is the most certain means of differentiating" displacement from transposition of the heart.

The prognosis of such a patient's disease is uninfluenced by the existence of the anomaly. Gruber

*Presented before the Northern Medical Association, December 12, 1924. From the Department of Medicine, Jefferson Hospital.

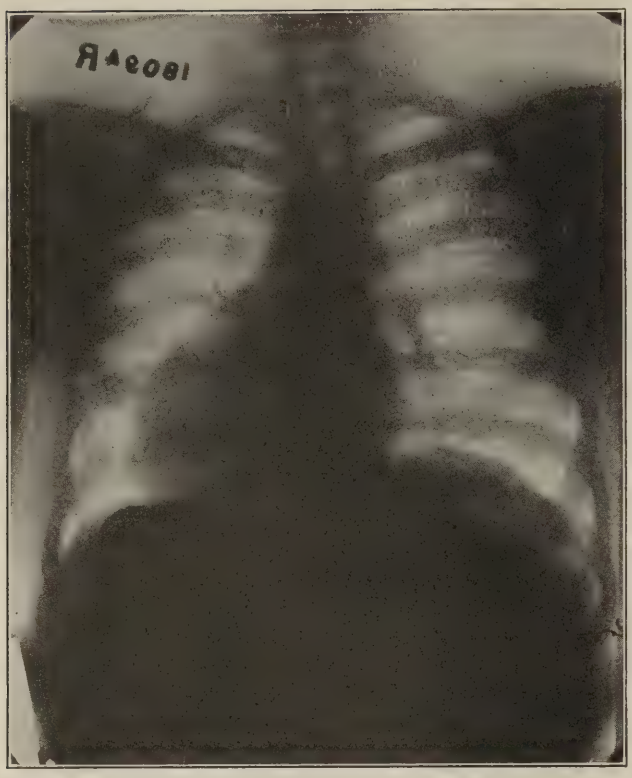

Fig. 1.—Transposition of the heart. The right diaphragm is lower than the left, and the liver is on the left side.

Fig. 2.—Transposition of the pylorus, duodenum, cecum, and sigmoid flexure of the colon.

(5) found five of the nineteen females lived to an age of between seventy and eighty-four years.

The following four cases present the very rare incidence of two members of one family having this condition. There was no complaint referable to the anomaly in any one of them. All were of average intelligence, right handed, and showed no outward abnormality. No other member of the three unrelated families showed any gross anomaly.

Case I.—A. B., a girl nine weeks old, was brought in for treatment for her cough. The heart appeared to be on the right side of her chest. Eight months later, February, 1918, she had an attack of lobular pneumonia, from which she made an uneventful recovery. Subsequent reexaminations confirmed liver dullness on the left side, and gastric tympany on the right.

Case II.—P. L., a boy of nine years, was found to have the heart sounds on the right side of the chest. He was born prematurely, at seven months, and is said to have weighed four pounds. His family and past personal history was of no clinical importance. His apex beat was visible and palpable on the right side, fifth interspace, at the midclavicular line. The left border of cardiac dullness corresponded to the left border of the sternum, the right border was 8.5 cm. to the right of the midsternum. An apical systolic murmur not transmitted, was audible after exertion. Percussion revealed hepatic dullness to be on the left side, and gastric tympany and splenic dullness were clearly demonstrable on the right. The spleen was not palpable.

Case III.—H. H., male, twenty-eight years of age, complained of backache. Examination revealed the heart signs on the right side of the chest, liver dullness on the left, and gastric tympany on the right side. He had a positive Wassermann, and proved to have tertiary syphilis.

Case IV.—A. B., a sister of H. H., was discovered in the course of examination of the other thirteen members of the three generations of the family. She was twenty-three years old, married. Her family and personal history was negative. She had given birth to four boys, two of them twins. One of the twins succumbed to socalled yellow jaundice at the age of two months. She did not know whether the infant had any anomaly. She had all signs of a normal heart in the right side of the chest. Liver dullness was found on the left, and gastric tympany and splenic dullness on the right.

Röntgenographic examination of the four patients showed transposition of the heart, the apex being on the right side. The right diaphragm was lower than the left. The liver was shown on the left side (Fig. 1). Cases II, III and IV showed the cardiac end of the stomach on the right side. The pylorus, the first portion of duodenum and the cecum were on the left, and the sigmoid flexure of the colon on the right, indicating a transposition of the stomach, pylorus, duodenum, cecum and sigmoid flexure of the colon (Fig. 2). Electrocardiographic studies were made of Cases II, III and IV which illustrated the transposition of the heart.

SUMMARY

Four cases of transposition of all the viscera are reported, two of them being members of one family.

The simplest way to diagnose transposition of the viscera is to make a careful physical examination of the patient's bared chest and abdomen.

Electrocardiograms and references will be published in the author's reprints.

Experiences with Cholecystography*

MAX EINHORN, M.D., WILLIAM H. STEWART, M.D.
and E. J. RYAN, M.D.,
New York

(*From the Lenox Hill Hospital.*)

Recognition of biliary tract diseases has been greatly advanced by the direct examination of the bile and by röntgenography of the gallbladder area. Up to a short time ago the x ray showed gallstones in about twenty-five to thirty-five per cent., and gallbladder lesions by indirect evidence, concavity of cap or fixation of the latter to the under surface of the liver by gallbladder adhesions. In another group of cases the shadow of the gallbladder could be recognized and was then usually considered pathological. Inasmuch as seeing an object is our greatest asset for becoming well acquainted with it, it must be considered of greatest importance to possess a method of actually visualizing the gallbladder. This has been accomplished by Graham, Cole and Copher (1 and 2) by the intravenous injection of the sodium salt of tetrabrom or tetraiodo phenolphthalein.

Regarding the intravenous injection of this new method of examination of the gallbladder the above mentioned authors give the following instructions:

"Four and five tenths to five grams of the sodium salt of tetrabrom phenolphthalein are dissolved in forty c. c. of freshly distilled water and filtered. It is then given intravenously with a syringe in two doses, one half hour apart, when fasting. Care should be taken not to allow extravasation into the extravascular tissue on account of the danger of tissue necrosis. The injection is given between 7:30 and 9:30 a. m. and the following rules observed:

1. Omit breakfast.
2. Omit lunch. (A glass of milk may be given if hungry.)
3. Take sodium bicarbonate 2.6 grams every three hours for forty-eight hours.
4. Lie on right side of abdomen or be up.
5. Take water.
6. Omit protein from the evening meal when injected.
7. Take x ray at four, eight, twenty-four and thirty-two hour periods.

"Dizziness and vomiting are occasionally observed following the injection, also a slight drop in the blood pressure, which is greatly helped by the intramuscular injection of adrenalin (1:1,000) 0.5 to one c. c."

Graham and his coworkers give the following summary of their work:

1. Cholecystography has been shown to be possible by a variety of substances.
2. The criteria that distinguish the normal from the abnormal biliary tract have been established.
3. With the aid of this method we have been able to make a correct diagnosis in ninety-five per cent. of the cases of cholecystitis, with or without stones, which it has been possible to verify by operation and pathological examination of the gallbladder.
4. This method has proved to be accurate, even in cases of very early cholecystitis.

*Read before the American Gastroenterological Association, May 26, 1925, at Atlantic City, N. J.

Gosset and Loewy (3) have employed the tetrabrom phenolphthalein intravenously for the x ray visualization of the gallbladder and have been satisfied with the results. They mention unpleasant symptoms in some of their cases, which, however, passed off without any serious disturbances. These writers also made use of cholecystography in combination with barium in the x ray examination of the stomach and duodenum in order to show the relations of the gallbladder to the duodenum. This method is of great import in the differential diagnosis between cholecystitis and pyloric or duodenal ulceration.

Since June of last year the authors have undertaken a study of this new important procedure on a greater number of patients and take pleasure in reporting their results.

For brevity's sake we compiled a table showing the names of all the patients in which the Graham test by the intravenous injection was applied, stating the results obtained. In one case of this series the tetrabrom phenolphthalein was given through the duodenal tube, inserting the solution into the descending portion of the duodenum.

Table I is a review of cases in which the sodium tetrabrom phenolphthalein was given according to Graham, Cole and Copher. We find the following:

In about ninety per cent. of the cases the shadow of the gallbladder was distinct, and permitted us to say whether there was any pathological condition of this organ, with regard to form, size, location and function. In ten per cent. of the cases no distinct shadow could be seen, indicating obstruction of the cystic duct or thickened wall gallbladder.

In a number of cases in which the usual examination of the gallbladder region gave a negative shadow with regard to the presence of biliary calculi, the Graham test showed stones very distinctly. This is due to an imbibition of the upper layers of the calculi with the bromide salt or the negative shadows cast by soft gallstones when in contact with the opaque bile.

Thirteen patients of the cases reported in this table have been operated upon. The results of the operative findings tallied in all with regard to the pathological condition of the gallbladder, and also with regard to the presence of stones, excepting one.

Of the thirty-eight cases thirty-one showed reactions in the nature of slight nausea, headache and vomiting after the tetrabrom salt. In the majority of cases the reactions were mild and passed off very rapidly. In a few, however, the reactions were quite severe. Among these we encountered severe vomiting, chills and fainting.

Silverman and Menville (4) have employed the Graham method in order to decide whether nonsurgical biliary drainage is possible and have arrived at the following conclusions:

TABLE I

CASES IN WHICH CHOLECYSTOGRAPHY WAS PRACTISED AFTER PREVIOUS INJECTION OF TETRABROMPHENOLPHTHALEIN (IN THIRTY-SEVEN CASES INTRAVENOUSLY AND IN ONE DUODENALLY).

Name	4 hrs	8 hrs.	24 hrs.	No Shadow	Op. Findings	Bile Findings	Reaction
T-n	..	..	+	..	iLS	Coal black, tarry, turbid, cholest. and bunchberry crystals.	Nausea[1]

Remarks

[1]Large stone visible surrounded by an opaque ring.

[2]Patient intensely icteric; four stones are visible.

[3]In the gallbladder shadow, four big stones lying on each other are visible.

[4]In the gallbladder shadow, six big stones are visible.

[5]Patient icteric. At operation the gallbladder was found embedded in dense adhesions and the cystic duct compressed by an enlarged chronically inflamed pancreas.

[6]Gallbladder previously drained.

[7]Previous cholecystectomy. The test was made in order to see whether the gallbladder will be found absent.

[8]Situs Inversus. The gallbladder shadow was here found on the left side, under the liver.

[9]Given by the duodenal tube.

[10]The gallbladder was found very much enlarged (three to four times the normal size) indicating distinct pathology.

[11]A very small gallbladder, similar in size to the small finger was found. The operation confirmed the x ray findings.

"1. The duodenobiliary drainage following a single stimulation with magnesium sulphate solution produces a reduction in size and alteration in shape of the gallbladder shadow when visualized by the Graham method. Plates taken at intervals up to twenty-four hours after the injection of the dye, but without drainage, show no parallel diminution in size or alteration in shape of the shadow.

"2. Since nonsurgical biliary drainage reduces the size and alters the shape of the gallbladder, we are led to conclude that drainage of the gallbladder does take place."

Anyone who looks over the pictures given by Silverman and Menville will arrive at the following conclusions:

Fig. 1 appears smaller than Fig. 2 with regard to the gallbladder shape. This contradicts the statement that the gallbladder without magnesium sulphate drainage never changes in size or shape. Comparing Fig. 3 (gallbladder thirteen hours after injection of the dye and immediately before nonsurgical biliary drainage) with Fig. 4 (gallbladder shadow after nonsurgical biliary drainage of twenty minutes' duration; reduction in size and alteration in shape of gallbladder shadow) you will notice that there is no reduction in size in Fig. 4 as compared with Fig. 3, Fig. 4 looking rather larger. The only difference with regard to shape is that in Fig. 4 the neck of the gallbladder seems narrowed.

We have made a few experiments regarding this question in four patients. The procedure was as follows:

First we ascertained whether peptone or magnesium sulphate instilled into the duodenum produced a good color reaction (i. e., dark bile). The following day tetrabrom phenolphthalein was injected and as soon as the röntgen examination demonstrated the gallbladder, either peptone or magnesium sulphate was instilled into the duodenum and a half hour later another observation made. The gallbladder shadow before the instillation could thus be compared with the one taken after the instillation of the peptone or magnesium sulphate. We give these experiments in the following table:

TABLE II

		Gall bladder visible after 4 hrs.	24 hrs.	Substance Instilled	Shrinkage
1.	T.	+	..	Peptone	None
2.	S.	+	..	Magnesium sulphate	Slight
3.	S.	+	..	Magnesium sulphate	None
4.	S.	..	+	Peptone	None

The table shows that there was once a slight shrinkage of the gallbladder after the magnesium sulphate while in the other three there was no change in the size of the gallbladder. The absence of an emptying of the gallbladder was noted notwithstanding the fact that all of the four patients gave distinct color reaction when the duodenal contents were drained after the peptone or magnesium sulphate instillation.

The experiments seem to indicate that the color reactions in these four cases were not due to the appearance of concentrated gallbladder bile (due to an emptying of this organ) but rather to the increased action of the liver (provoked by the instilled substance).

The necessity of administering the tetrabrom

Fig. 1.—Preliminary examination of the gallbladder before intravenous injection. (S-l)

phenolphthalein salt intravenously is a drawback for its widespread clinical use. An attempt was made to administer it through the duodenal tube, instilling the dye into the descending portion of the duodenum or in the beginning of the jejunum. However, the röntgen examination of the first patient gave a negative result. An article by L. R. Whitaker and Gibbs Milliken (5) suggested to us the use of sodium tetraiodo phenolphthalein. We were eager to test this substance in order to see whether the unpleasant symptoms occasionally occurring with the tetrabrom salt could not be obviated. Furthermore, we decided to administer the sodium tetraiodo phenolphthalein tentatively, both by the jejunal and oral methods.

Fig. 2.—(Same patient as in Fig. 1) Four hours after intravenous injection of tetrabrom phenolphthalein. Gallbladder visible with several large stones in same. (S-l)

In their important article Whitaker and Milliken arrive at the following conclusions:

"On account of the greater atomic weight of the iodine sodium tetraiodo phenolphthalein should be nearly twice as opaque to the x ray as sodium tetrabrom phenolphthalein.

"In practice nearly twice as much of the bromine salt as of the iodine salt is required to obtain a shadow of the gallbladder.

"Our experiments indicate no appreciable difference in the toxicity of the two drugs. Consequently for use in biliary cystography there appears to be a wide margin of safety in favor of sodium tetraiodo phenolphthalein over the analogous bromine compound."

Graham, Cole and Copher (6) coincide with Whitaker and Milliken that sodium tetraiodo phenolphthalein is preferable to the tetrabrom salt. They are now using it for cholecystography because smaller

Fig. 3.—Eight hours after intravenous injection of tetrabrom phenolphthalein. One stone visible in the form of a large ring. (T-n)

doses are sufficient to produce a shadow of the gallbladder. They administer 3.5 grams intravenously to patients weighing sixty kilos and have fewer and less marked reactions. The same technic is used as for the tetrabrom salt. Applying these substances orally the above authors have had variable and inconstant success in obtaining gallbladder shadows and prefer the intravenous method.

I. O. Palefski (7) administered two to four grams of sodium tetrabrom phenolphthalein through the duodenal tube. He obtained satisfactory gallbladder shadows and has seen no toxic effects. S. Weiss (8) has also given the tetrabrom phenolphthalein through the duodenum and rectum.

Based upon these statements we started to employ the sodium tetraiodo phenolphthalein for cholecystography, giving it, however, jejunally and orally instead of intravenously. At first four grams was given through the duodenal tube. Patients had unpleasant symptoms accompanied by vomiting and diarrhea. Notwithstanding the accidental loss of

Fig. 4.—(Same patient as in Fig. 3) Twelve hours after the intravenous injection of tetrabrom phenolphthalein. Stone more distinct. (T-n)

Fig. 5.—Eight hours after intravenous injection of tetrabrom phenolphthalein. Gallbladder visible and enlarged. Two stones in it and two probably in a dilated common duct. (W-r)

much of the tetraiodo salt the gallbladder shadow appeared quite distinctly in the röntgenograms. This showed that a smaller amount would be sufficient for our purpose. The dose was then reduced to two grams and given jejunally to seven patients. The gallbladder was satisfactorily mapped out in all the röntgenograms taken but two patients of this group complained of unpleasant symptoms, suffering from vomiting and shock. It was necessary to give them adrenalin and stimulation besides. The symptoms passed over in about six to twelve hours and the patients were completely recovered the following day.

These unforeseen symptoms compelled us to reduce the dose to 1.5 and 1.75 grams and the following rules were instituted:

The evening before administering the tetraiodo salt the bowels should be cleansed but no strong cathartics such as castor oil used. At the same time a preliminary examination of the gallbladder should be made. In patients who are not on duodenal feeding the tube should be inserted the night previous to the examination. At 6 a. m., provided the tube has reached the jejunum, give two hundred c. c. of milk (blood temperature) through the tube. At 8 a. m. one hundred and fifty c. c. of one half per cent. solution of the sodium tetraiodo phenolphtha-

Fig. 6.—(Same as 5) Twelve hours after intravenous injection of tetrabrom phenolphthalein. Gallbladder visible with one stone in same. Three stones in the dilated common duct. During the period between eight and twelve hours one stone has moved over from the gallbladder to the common duct. (W-r)

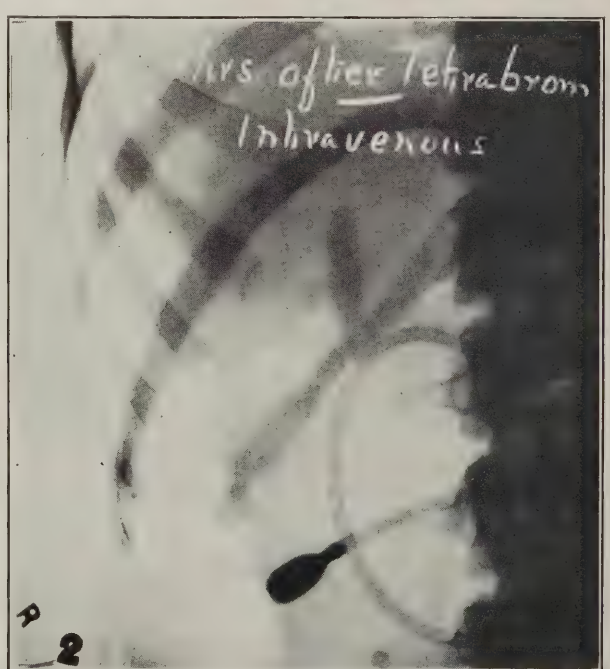

Fig. 7.—Twenty-four hours after the intravenous injection of tetrabrom phenolphthalein. A small contracted thickened wall gallbladder with a lumen of the size of a little finger visible. At operation a small thickened gallbladder, about the size of a little finger, was found. (S-r)

lein is instilled (slowly and at blood temperature) into the jejunum. After an interval of one half hour the same amount is again administered in like manner. The patient is requested to abstain from food from eight to twelve o'clock and remain in a quiet position. X ray examination of the gallbladder region is made at twelve o'clock followed by slight nourishment. At 4 p. m. and at 9 a. m. the following day further observations are made. Occasionally a röntgenogram is taken thirty-six hours after the administration of the tetraiodo.

The tetraiodo phenolphthalein was given jejunally to fifteen patients. Among eight patients to whom 2.0 per cent. solution was instilled there were severe reaction, nausea, faintness, shock, cold perspiration. In one of these cases the liver (Br) at the time of the reaction was considerably swollen; pulse fast and very thin; some dyspnea. After injecting adrenalin and stimulation with hot beverages patients recovered and were all right the following day.

Trying to avoid the reactions of the tetraiodo we gave 1.5 per cent. to 1.75 per cent., and in one patient with a weak heart 1.0 per cent. In all these cases there was practically no reaction.

The röntgenograms of the gallbladder with these smaller doses are less sharp than with the larger doses but sufficiently distinct to establish the exact shape of the organ. Our first and most important aim must be to minimize the dangers of the procedure and for this reason we recommend the use of the smaller doses.

In all fifteen patients the information regarding the gallbladder was important. In fourteen the gallbladder could be distinctly made out. In one patient (S), the fifteenth, with chronic jaundice, there was no gallbladder shadow present, due probably to occlusion of the cystic duct. The operation performed on this patient by DeWitt Stetten revealed two mulberry stones in the gallbladder, which contained no bile; occlusion of the cystic duct of an inflammatory type and chronic pancreatitis.

The tetrabrom as well as the tetraiodo phenolphthalein are likely to bring out the liver shadows and in some cases also the kidney shadows more clearly than when examined before the administration of this dye.

In some cases, therefore, it might be helpful to examine these organs after the employment of these dyes.

ORAL METHOD

Investigations made by the authors supported by results reported by M. Sosman, of Boston, Mass., who is using tetraiodo made up into pills and coated with salol, T. O. Menees and H. C. Robinson, of Grand Rapids, who are using tetraiodo in formaline hardened gelatine capsules, and L. R. Whitaker, Gibbs Milliken and Edward C. Vogt, of Boston, who now coat their tetraiodo pills with stearic acid, convinced us that the drug could be given by mouth and satisfactory results achieved. We now routinely use the oral method in all cases referred to our office for röntgenographic examination of the gallbladder.

The method of procedure is as follows: After a thorough cleansing of the intestinal tract, preferably by a turpentine enema, a preliminary examination of the gallbladder is made in the regular manner at

FIG. 8.—Eight hours after jejunal instillation of tetraiodo phenolphthalein. Gallbladder and a number of stones of varying sizes distinctly visible. (M-n)

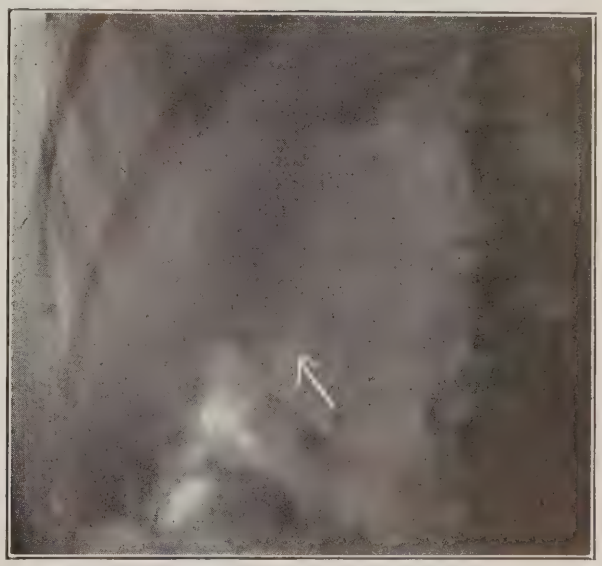

FIG. 9.—Eight hours after jejunal instillation of tetraiodo phenolphthalein. Gallbladder considerably enlarged. (B-t)

FIG. 10.—Four hours after jejunal instillation of tetraiodo phenolphthalein. Gallbladder immensely enlarged. (L-s)

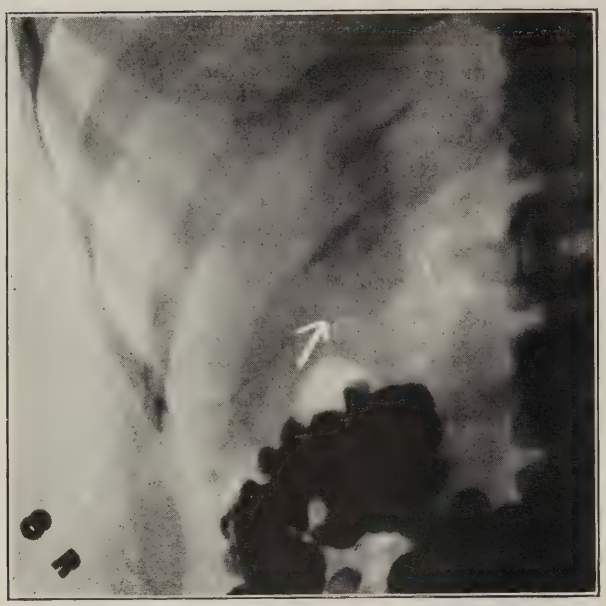

Fig. 11.—Twelve hours after oral administration of tetraiodo phenolphthalein. Gallbladder visible. Mottled appearance indicating small stones. (S-r)

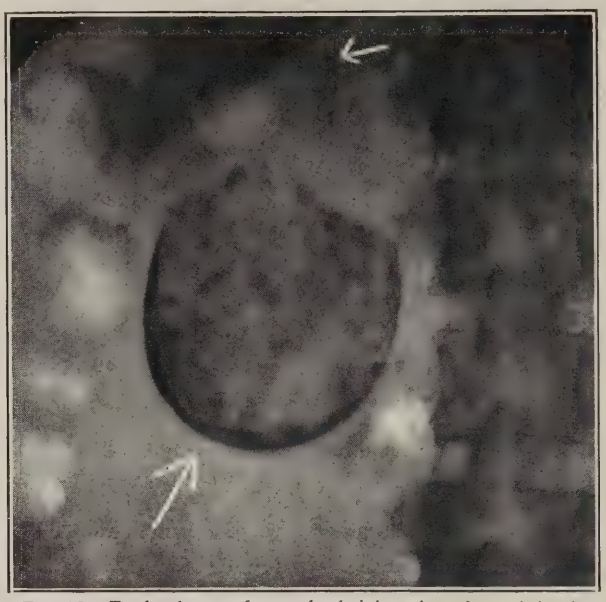

Fig. 12.—Twelve hours after oral administration of tetraiodo phenolphthalein. An immense gallbladder with calcified wall seen and in it numerous small stones. Operation confirmed these findings. (M-y)

10 a. m. The usual lunch is then allowed; at 6 p. m. a light supper is advised.

Forty grains of the tetraiodo phenolphthalein sodium salt, having been freshly made into eight five grain pills well coated with keratin or mutton tallow, the patient is instructed to commence at 9 p. m. and take two pills with a wine glass of water every fifteen minutes until all are taken.

At 8 a. m. the following morning a cup of coffee and one roll is allowed. At 10 a. m. the first röntgenographic examination is made. Four hours later, at 2 p. m., the examination is repeated. Regular lunch is served at 2:30 p. m., followed by another x ray examination at 4 p. m. The final observation is made the following morning thirty-six hours after the administration of the tetraiodo salt.

It is essential to make the preliminary examination before the administration of the tetraiodo to ascertain if there are any gallstones visible or shadows indicating a pathological gallbladder.

The starvation diet is necessary in order that the gallbladder may become distended with the opaque bile. The best outline is usually obtained at 2 p. m., sixteen hours after the tetraiodo. As soon as food is given the gallbladder, if normal, contracts and slowly empties as shown by the diminution in size and the more sharply defined detail to the shadow.

So far our patients submitting to the oral method, fifty-three cases in all, have had no serious reaction. About ten per cent. had a vomiting attack and perhaps twenty-five per cent. a slight nausea—five cases had a mild diarrhea.

TECHNIC

One must not be led to believe that with completion of the administration of the media the worst is over; these cases try the skill of the röntgenologist to the limit. Every known technical requirement is necessary to obtain satisfactory results.

Particularly should we gain the confidence of the patient; this is best accomplished by a quiet explanation of what is to be done and the purpose of the x ray examination. The patient should be carefully instructed to suspend respiration at full inspiration so that the gallbladder will be brought down to the lowest possible level. Full inspiration does not mean such a tremendous effort that the body is trembling from tension. Perfect relaxation is ideal. Never hurry your patient. Explain that plenty of time will be given for all requirements before the exposure.

The patient lies on the table, abdomen down with the chest slightly raised so as to open the costal arch as much as possible. The body of the patient should have a slight tendency to the left; at least the face should always be toward that side—this will throw the gallbladder shadow away from the spine, a fine technical point but most important, for in more than one instance gallstones have been overlooked by overlapping shadows of the vertebra.

The röntgenographic technic for gallbladder examination is variable. At the present time we prefer to use the Potter Bucky diaphragm with firm compression; a small cone at a distance of twenty-eight inches, a fine focus gas tube taking thirty-five milliamperes backing up about four inches and an exposure in an average individual of about three seconds. Double screens and films are used.

At least six films should be made at each visit to the röntgen department, for many may be worthless on account of some respiratory effort made by the patient during the exposure.

SUMMARY

Cholecystography (according to Dr. Graham) has found a permanent important place in medicine. The intravenous injection of tetrabrom phenolphthalein is frequently accompanied by reactions, which at times are of a severe type.

The administration of tetraiodo phenolphthalein by mouth or jejunum, not in large doses, is accompanied by less reactions, and is therefore preferable to the intravenous method.

We are indebted to Eggers, Erdman, Fischer, Garbat, Hensel, Willy Meyer, Sanders, Stetten and Torek for allowing us to use some of their cases.

The Itching Skin a Symptom of Systemic Disease*

WILLIAM H. GOECKERMAN, M.D.

Rochester, Minnesota.

The dermatologist must still retain a somewhat cumbersome descriptive nomenclature. Even when the etiology has been fairly definitely established, the various skin pictures may not be designated merely by terms referring to the etiological agent. As an illustration I need only call attention to the necessity for classifying the variable objective manifestations of cutaneous tuberculosis. Nevertheless, dermatology cannot be approached with scientific seriousness without paying particular attention to the relationship of dermatoses to functional, pathological and biochemical changes in the body economy. There are, to be sure, a number of dermatoses which are apparently produced solely by parasites, but even the parasites need a favorable somatic soil to gain a foothold.

Neisser always emphasized the close relationship between dermatoses and systemic disease. His monumental studies on syphilis, leprosy, tuberculosis, and gonorrhea are witnesses to his viewpoint. He considered these diseases admirably adapted to demonstrate such a relationship.

Even the esoterist in morphological dermatology can obtain little but artistic satisfaction from a study of the lesions of the skin unless he approaches such study from the broad pathological viewpoint. The attitude of the investigating naturalist rather than that of the specialist must be assumed. With such an attitude, dermatoses, which are often regarded by the practising physician as a *noli-me-tangere,* will secure wider general interest. With this attitude it seemed to me that it would be of interest to discuss the itching dermatoses, especially emphasizing the somatic background in the light of general pathological principles. The etiology of many of these diseases has not been established, yet modern observations allow of interesting theories. Such an approach to dermatology simultaneously affords an opportunity to emphasize the necessity of a careful clinical and laboratory study of the patient, and to condemn the common practice of merely prescribing some local antipruritic.

*Submitted for publication May 25, 1925. Section on Dermatology, Mayo Clinic.

DERMATOSES WITHOUT CHARACTERISTIC SYMPTOMS

No group of dermatoses illustrates better the importance of systemic disease in the production of lesions of the skin than that comprised under the term toxic pruritus. As the name implies, the itching is the result of a toxic process, usually due to a disturbance in metabolism. The diagnosis can be made from the absence of all characteristic manifestations except those of a secondary character, such as pigmentation, excoriation, lichenification, and pyogenic infection. With some practice the diagnosis is readily made, and it then becomes necessary to cover almost the entire field of internal medicine in a search for the cause underlying the disturbance. For practical purposes, in cases of toxic pruritus, I examine carefully for the following diseases: 1, lymphogenic diseases, particularly Hodgkin's disease and lymphosarcoma; 2, hyperthyroidism and hypothyroidism; 3, chronic nephritis; 4, arteriosclerosis with or without senile skin changes; 5, enlarged prostate; 6, chronic intoxication due to drugs (opium and cocaine, coffee, tea, and so forth); 7, chronic disease of the liver and gallbladder, even without jaundice; 8, abdominal malignancy; 9, functional and organic nervous diseases; 10, diabetes, and 11, focal infections.

In the lymphogenic diseases itching is often the first annoying symptom. The patient is in seemingly excellent health and unless the underlying disease is suspected it is readily overlooked. A röntgenogram of the chest will often reveal a mass of enlarged nodes in the mediastinum, when superficially none is in evidence. Occasionally a sedulous search for nodes in the groins, axillæ, or cervical region will reveal one of unusual size. If the diagnosis has not been reached by other methods, such a node should always be removed for microscopic examination. We have thus been able repeatedly to clinch the diagnosis early. Patients often have severe pruritus for years before their general health declines. A patient was recently observed at the clinic who gave a history of severe itching for more than five years. When examined here he had extremely large axillary nodes. A specimen from one of these revealed a lympho-

sarcoma. Filtered röntgen ray treatments to the glands afforded marked symptomatic relief. The patient's local physicians had pronounced it the seven-year itch, and the patient was ready to bear the itching for another two years.

FUNCTIONAL DISEASES OF NERVOUS SYSTEM

I need not go into detail in regard to the other diseases enumerated. A careful history and physical examination should in most cases give a correct diagnosis. I would, however, like to emphasize a few points in regard to the functional diseases of the nervous system. Every effort should be made to exclude organic disease. It is only too easy to suspect a functional nervous background in these patients since the prolonged severe itching with its concomitant loss of sleep has often made them very irritable and unreasonable. Moderate hyperthyroidism is especially prone to be overlooked. It has occurred to me that in the purely functional types of disease the itching is likely to be more or less localized. Sometimes it is the upper back, again the extremities, or some other part where it is particularly troublesome. When the itching localizes in the genital, perineal, or anal region, the disease is especially likely to be of a functional type. In such cases, however, careful search should be made for pelvic, rectal, and local cutaneous disease. In my experience this localized pruritus is usually not relieved, even when such abnormalities as hemorrhoids, rectal fissures, cervical scars or ulcerations, and displacements of the uterus, are treated. It is difficult to escape the impression that this type of pruritus is a definite psychogenic disorder. Sometimes mental complexes with reference to experiences connected with the genital sphere can be elicited by psychoanalysis. In this event such treatment will bring marked or complete relief.

In the functional group we will probably also have to consider the socalled pruritus estivalis and pruritus hiemalis, the phenomenon that certain persons itch in cold and others in warm weather. Closely related in its nature is the itching which troubles certain persons when wool or flannel is worn next to the skin, when undressing, or when cold linen touches the skin. Many of these patients have an unusually smooth pliable skin which is dry from lack of the usual amount of oily secretion. These patients are often much relieved by some emollient.

Pruritus senilis is probably explicable by the process involved in senile involution of the skin rather than on a functional basis. We know that not only the corium but also the epidermis, nerve end organs, and sebaceous glands undergo degeneration.

URTICARIA

A borderline position between toxic pruritus and the forms of pruritus with symptoms characteristic of dermatosis, is occupied by urticaria. We do not as yet fully understand the etiology of urticaria. Experience teaches that urticarial wheals are commonly observed after exposure to certain plants and insect bites, after the consumption of certain foods and medicaments, after certain mechanical irritations of the skin surface, and in the wake of certain psychic states.

Whether or not urticaria is a true inflammation need not be discussed here. There is practically no doubt but that there is a definite involvement of the nervous system; otherwise there would be no itching. It can probably also be assumed that there is some abnormality in the mechanism of the cutaneous cell and some biochemical disturbance in the other body tissues. The strawberry urticaria is particularly instructive in this connection. The ordinary chemism of the human skin is not so constituted that it will respond to the ingestion of strawberries with the formation of wheals. It would seem plausible, therefore, to assume the presence of a chemical acting somewhat as a sensitizing agent. In this connection it is striking to note that uric acid has often been found to be increased in the blood. The presence of histamin and cholesterin in the blood has been suspected. Many observers would like to look on urticaria as the result of protein sensitization. All these conceptions need further study, however.

DERMATOSES WITH CHARACTERISTIC SYMPTOMS

Of the dermatoses with the characteristic symptoms of itching, only those commonly seen will be discussed, as the rarer types have received insufficient study from the viewpoint of general pathology. In the former are included: 1, granuloma fungoides, 2, dermatitis herpetiformis, 3, lichen planus, and, 4, eczematoid dermatitis. I am ignoring scabies and pediculosis because they are not germane to the subject.

Mycosis fungoides is closely related to leucemia. A discussion of their relationship would be idle, however, since the exact etiology of neither is known. It is important that a diagnosis be reached early because it is only in the early stages that definite therapeutic results can be hoped for. Radiotherapy in combination with arsenic, either by mouth or injection, is the method of choice. Antipruritics locally are of no value except for the temporary relief from itching which they may afford.

Dermatitis herpetiformis is not so sharply defined in its clinical characteristics that we are justified in accepting a uniform etiology. There are cases in which it is difficult to distinguish between erythema multiforme and dermatitis herpetiformis, others again border closely on pemphigus. Another group will at one time show a dermatological picture of erythema multiforme, and at another time that of dermatitis herpetiformis, and in still another that of pemphigus. One group of authorities favors the view that bacteria or their toxins affect the nervous system and thus produce the eruption and its itching and burning. Another group is more inclined to believe that this disease is not of hematogenous origin.

Lichen planus is so characteristic in its manifestations that the assumption of a definite pathogenic process is plausible. We are still forced, however, to look on it purely in the light of clinical empiricism. Whether the process is purely local or whether it is a systemic disturbance is at present undecided. A nervous factor is commonly accepted because it is so often seen in association with psychic shock, anxiety, overwork, insomnia, excitement, and neuralgia. I have seen persistent lichen planus disappear promptly after the removal of several infected teeth. A bacterial etiology would be consistent with its histopathology.

Eczematoid dermatitis can probably not be considered an entity. It is difficult to escape the clinical impression that this skin picture is produced by two causes: the predisposing cause, a certain biological status, and the precipitating cause, the irritating substance responsible in the individual case. That there is a predisposing cause is probably best demonstrated in the professional and industrial dermatitis. It is often noted that probably only one of several persons exposed to the same irritating agent will show evidence of dermatitis. Just what change in the biochemical constituents is responsible for the predisposition has not been determined. It is entirely possible that changes in the blood and tissues are the results of various causes. In years past it was a fond belief that eczema was closely related to gout and merely one of the expressions of a gouty diathesis. This was of course based purely on clinical observation. Studies recently undertaken with reference to the chemistry of the blood show an excess of uric acid in a goodly percentage. Pulay believes that the tissues also contain an excess. Many authorities hold that eczema is an expression of the socalled exudate diathesis, analogous to hay fever, asthma, gout, and migraine. This assumption offers a fair working basis. It permits us to search for a history of hypersensitiveness to certain plant and animal proteins and subsequent desensitization or avoidance of the offending agent as in hay fever, the proper modification of the diet as in gout, and the regulation of the habits as in migraine.

It has been suggested that a deficient epinephrin content in the blood might account for the hypersensitiveness. The fact that eczema is often associated with low blood pressure and asthma, both benefited by epinephrin, lends color to this suggestion. It must be remembered, however, that the reduced epinephrin content may be merely the expression of intoxication. Lane seems to have shown that exophthalmic goitre may be the result of intestinal toxins.

In view of the clinical observation that eczema is very frequently associated with gastrointestinal disturbances, a close relationship would seem plausible. I believe that this relationship is best illustrated by the infantile eczemas, in which diet has been held responsible by most observers. Eczema has been attributed to the fats, to the proteins, and again to the carbohydrates, or to fermentation products in the intestine. It is entirely possible that all of these factors, and at times others, may be responsible. It is very probable that cases will have to be considered individually. We must remember that "one man's meat is another man's poison." As yet too little is known about the interaction and efficiency of the endocrine organs to determine what foods may have a deleterious effect in individual cases. The varying sugar tolerance in different, apparently healthy, persons is a case in point. I have seen a resistant case of infantile eczema clear up permanently after the elimination of butter from the diet, yet this same procedure may not benefit others at all. We are all familiar with the improvement observed when sweets are removed from the diet of an overindulged child.

At the Mayo Clinic certain children have been placed on extremely low fat, and others on very low carbohydrate diets without consistent results in either group. At present we favor a well balanced mixed diet, carefully observing the patient's stools and his weight and general reaction to the diet. Skin sensitization tests have not helped in the clinical management of these patients.

Certain authorities believe in neurogenic influence in eczema. The clinical study of patients frequently makes this theory seem plausible. It also gains support from certain definite scientific observations on the sugar metabolism. We are familiar with the glycosuria in certain nervous individuals. It has been demonstrated that venipuncture often suffices to produce hyperglycemia. It is conceivable that in such patients every excitement and every psychic insult leads to a hyperglycemia and thus to very definite metabolic disturbances.

In many of these patients a hypercholesterinemia is found. The significance of this is not as yet known, but it seemingly points to an abnormal metabolism as it is frequently associated with internal diseases almost certainly of metabolic origin.

There may be a disarranged relationship between food intake and consumption, either because of a poorly balanced or superabundant diet, or because of lack of the proper activity to dispose of the end-products of digestion.

Interesting also are the observations on the blood calcium. It has been shown experimentally that animals fed with calcium are less prone to exudative processes, whereas animals given large quantities of sodium will have a reduction of calcium. The calcium content in eczema has often been found to be low. This leads Pulay to the conjecture that, since calcium stands first in the cationic series with relation to its protein "swelling" qualities, it may counteract the shrinkage of the cells, which manifests itself clinically as an exudation.

While these various conceptions are as yet purely theoretic, they permit of a systematic approach to treatment. Each case should be studied separately and carefully to determine whether the evidence points most strongly to a neurogenic, dietetic, metabolic, toxic, or infective factor.

In considering the precipitating causes of eczema, we are confronted by a myriad of possibilities. Eventually every organic and most inorganic substances may prove to be offenders: the chemicals as employed in the household, industries, arts, sciences, and professions; flowers as found in the hothouse, home garden and fields; weeds around the house, in the fields and woods; animals kept as pets and for economic reasons; the various grains and vegetables, and the effect of either artificial light or sunlight.

The object of this paper is to emphasize the importance of regarding an itching skin as a signal of systemic disturbance which needs adjustment before we can give the patient proper treatment. The habit of merely prescribing some local antipruritic, so often indulged in, brings discredit to the profession. Small wonder that a patient sometimes receives more benefit from suggestion, baths, massage, diet, and exercise prescribed by the faker. Each patient with an itching skin should receive close individual study, as the associated conditions are so variable. Only such careful consideration, looking farther than merely symptomatic relief, will result in permanent relief from the trouble.

Dercum's Method of Treating Neurosyphilis

D. L. KERLIN, M.D.
Shreveport, La.

Before presenting some of the cases of neurosyphilis which we have on record, and explaining our method of treatment, I shall give some of the important points which have been brought out by various authors in the use of the most popular methods of treating neurosyphilis. Judging from the literature and the report of various authors who have experimented extensively with it, tryparsamide is the drug of choice in treating neurosyphilis. Although it has not been released to the profession in general it will be, no doubt, in the near future, and to mention some of the important facts concerning its use as established by various clinicians will not be premature.

Tryparsamide contains twenty-five and thirty-two one hundredths per cent. arsenic and its characteristics as described by Brown and Pearce are as follows: 1, Comparative freedom from harmful effects; 2, a moderate degree of treponemicidal action; 3, an unusually high penetrability; 4, a remarkable power of reinforcing the processes of natural resistance and of promoting recuperation.

Lorenz and Loevenhart in a report of a hundred and eighty-five cases give the following conclusions in regard to the use of tryparsamide in neurosyphilis:

1. Tryparsamide and mercurial salicylate are therapeutically effective in early paresis, meningovascular syphilis and to a lesser degree in taboparesis, tabes, and advanced paresis.

2. The beneficial clinical results precede the improvement in the serology.

3. Definite paretic psychoses disappear as the result of treatment.

4. The mental restoration has persisted over a two year period.

5. Visual disturbances occurred in seven per cent. of the total number of cases treated.

6. In tabes and taboparesis twenty-three per cent. of the cases treated showed visual disturbances.

7. Of thirteen cases showing amblyopia during tryparsamide therapy, all but one cleared up after the withdrawal of the drug. Twelve of these cases were subsequently treated with tryparsamide without further eye disturbances.

8. A complete ophthalmological examination as to fundus acuity and visual fields should be done in every case before using the drug.

Tryparsamide is given in doses of three grams weekly for eight to sixteen injections. Injections of mercurial salicylate intramuscularly are either spaced in between the tryparsamide injections or given after the course of tryparsamide is completed. After a rest period, this course of treatment can be repeated if necessary.

The Swift-Ellis plan of treatment has many warm advocates and its technic as used by Fordyce is as follows: First, the usual injection of arsphenamine is given. Second, half an hour later, fifty c. c. of blood is withdrawn from the vein; this is placed on ice for four hours. Third, the blood is centrifuged and the serum is piped off under aseptic precautions. Fourth, this serum is inactivated by incubating at 56° C. for one hour. The object of this is to render inactive any bacteria that may be present in the blood stream. Fifth, a spinal puncture is done, the stylet is withdrawn, and at the same time the percolator is attached to the needle by a piece of rubber tubing six inches long. By holding the percolator below the level of the needle, the spinal fluid is allowed to flow into it. Then the inactivated blood serum is mixed with an equal amount of spinal fluid and allowed to flow through the needle by raising the percolator. Enough serum mixed with the spinal fluid is allowed to flow through the needle to replace the amount of spinal fluid withdrawn. The number of treatments vary with the severity of the infection. Fifteen to twenty-five injections constitute the average course.

We have used the Swift-Ellis method of treatment, but have not been pleased with it. We now use Dercum's method exclusively which consists of weekly injections of arsphenamine followed by spinal drainage. Following spinal drainage, on an average of three times in each case, we inject bichloride of mercury from one seventy-fifth to one ninetieth of a grain intraspinally. In addition, we give daily from one twelfth to one twenty-fourth of a grain of bichloride intravenously. When the veins become sclerosed and we can no longer inject the bichloride, we use weekly injections of potassium bismuth tartrate intramuscularly, spaced in between the arsphenamine injections. This treatment is continued until we get a negative spinal fluid Wassermann, and then bismuth is continued for at least ten injections. A spinal fluid analysis is done within three months and again in six months after treatment has been stopped. If found positive, further treatment is given.

Before giving you the results of this method in a few selected cases, I shall present some data on the serological findings in the various types of neurosyphilis:

I. PARESIS OR TABOPARESIS.

1. Wassermann reaction in blood positive (one hundred per cent.).
2. Globulin positive (ninety-five per cent.).
3. Lymphocytosis (ninety-five per cent.).
4. Wassermann spinal fluid.
   a. Positive in eighty-five to ninety per cent. with original method and two tenths c. c. of fluid.
   b. Positive in one hundred per cent. with larger quantities of fluid.

II. TABES AND CEREBROSPINAL SYPHILIS.

1. Wassermann reaction on blood positive in tabes sixty to seventy per cent. and in cerebrospinal syphilis eighty to ninety per cent.
2. Globulin reaction positive (ninety per cent.).
3. Lymphocytosis positive (ninety per cent.).
4. Wassermann on spinal fluid.
   a. Positive in five to ten per cent. with original method and two tenths c. c. fluid.
   b. Positive in one hundred per cent. with larger quantities of fluid.

TABOPARESIS

CASE I.—The patient, white, female, aged forty-five years, entered the sanatorium on April 10, 1924. Her family history was unimportant and her past history was also unimportant with the exception of an ectopic pregnancy for which she was operated on in 1922. Her menstrual history was negative, with no miscarriages nor still births.

Her present illness began four years ago when she began to feel irritable with depressed moods, frequent headaches and intestinal disturbances. On several occasions while driving a car she would suddenly feel faint with a sensation of blindness and would have to stop the car until the attack had subsided. Recently her memory had been defective, and there was marked muscular weakness and insomnia.

Neurological examination showed the Romberg, static ataxia, pupillary reflexes equal, regular in outline, reacting sluggishly to light and accommodation; speech and gait normal; cranial nerves intact; slight incoordination in upper extremities, deep reflexes of upper extremities normal; diminished bilaterally in lower extremities; sensation areas of anesthesia and hyperesthesia over body; superficial reflexes normal; circulatory, respiratory and gastrointestinal systems negative.

Laboratory report: Urine negative; blood Wassermann four plus; spinal fluid cell count 45, globulin increased, sugar sixty-five mgms. to one hundred c. c. Wassermann four plus in all antigens in smallest dilutions. Colloidal gold curve 5555443300.

Spinal fluid analysis: After five weeks' treatment: Cell count 80, globulin 28 mgms. to one hundred c. c. Sugar 110 mgms. to one hundred c. c. Wassermann; Kolmer antigen four plus. Cholesterinized antigen two plus. Noguchi antigen two plus. Colloidal gold curve 555534400. After four months' treatment: Cell count 3, globulin 16 mgms. per one hundred c. c. Sugar 65 mgms. per one hundred c. c. Wassermann one plus in all antigens. Colloidal gold curve 444420000. Six months after cessation of treatment: Cell count 5, globulin 15 mgms. per one hundred c. c. Sugar 65 mgms. per one hundred c. c. Wassermann negative in all antigens. Colloidal gold curve 144340000.

PARESIS

CASE II.—White male, aged sixty-two years. Entered sanatorium on September 8, 1923. His family history was unimportant. His past history showed that in 1921 he had had an attack of frequency of urination with a burning sensation. He was told by his physician that he had nephritis, but he refused treatment. He had a chancre thirty years ago, when he was thirty-two years of age, but no treatment was given at that time.

Present history: Two weeks previous to the time that we saw him, his symptoms were predominantly mental. His memory became defective, he had delusions of persecution, especially concerning women whom he thought were all trying to harm him; even his wife. Both visual and auditory hallucinations were present. His wife stated that he had been failing in health for the past six months; was very suspicious, irritable and forgetful.

Neurological examination: Romberg positive; pupils irregular in outline, unequal, right larger than left, reacted to light and accommodation sluggishly; marked arcus sensilis, and consensual and ciliospinal reflexes present; speech slurring; slight incoordination both upper extremities; tremor of both tongue and upper extremities; deep reflexes exaggerated, slightly more on left side; sensation normal; Babinski bilateral, more marked on left; circulatory, respiratory and gastrointestinal systems negative.

Laboratory reports: Urine: specific gravity 1.032, occasional hyaline and granular cast. Blood chemistry: creatinin 2.3 mgms. per one hundred c. c. blood. Uric acid 1.5 mgms. per one hundred c. c. blood. Urea 25 mgms. per one hundred c. c. blood. Blood Wassermann negative. Provocative blood Wassermann after two weeks on mixed treatment showed three plus in Kolmer antigen. Spinal fluid, four plus in cholesterinized and Kolmer antigens and negative in Noguchi in dilutions above two tenths c. c. Cell count 210, globulin increased, sugar normal. Colloidal gold curve 0055555432100.

Spinal fluid analysis: After one month's treatment, cell count thirty; globulin normal; Wassermann negative; colloidal gold curve 1333000000. After two and a half months' treatment, negative in every respect, including the colloidal gold curve.

CEREBROSPINAL SYPHILIS (MENINGOVASCULAR TYPE)

CASE III.—White female, aged twenty years; entered sanatorium November 11, 1924. Her family history was unimportant. Her past history showed removal of tonsils and adenoids when twelve years of age. She was of a very nervous temperament, and had suffered from indigestion for the past eight years. She menstruated regularly, but suffered from fainting attacks at time of menstruation. She has been treated for syphilis for the past two years. Up to the present time the patient had received twenty-two injections of salvarsan and eight injections of mercury, also mixed treatment. Blood Wassermann was positive up to July, 1924, when a negative report was received and treatment stopped.

Present history: The patient complained of a peculiar pressing sensation on top of head which she also experienced for one month in 1923. It returned this last time in January, 1924, following the sixth injection of salvarsan, and had continued to present date, November, 1924. She had a tendency to worry, was anxious over her condition, and had some social conflict.

Neurological examination: Romberg negative; pupils equal, regular in outline, reacting to light and accommodation; speech and gait normal; deep reflexes exaggerated all over; sensation normal; superficial reflexes present; circulatory, respiratory and gastrointestinal systems negative.

Laboratory reports: Urine negative; blood Wassermann one plus in all antigens; spinal fluid analysis, cell count 270, globulin 21 mgms. to one hundred c. c., sugar 75 mgms. to one hundred c. c., and Wassermann negative in all antigens; colloidal gold curve 4441000000.

Spinal fluid analysis: After six weeks' treatment, cell count 35, globulin 15 mgms. to one hundred c. c., sugar 65 mgms. to one hundred c. c., Wassermann negative; colloidal gold curve 5544332100.

The patient is under observation and a spinal fluid analysis will be made six months after the cessation of treatment.

SPINAL SYPHILIS (VASCULAR TYPE OF CERVICAL CORD)

Case IV.—White, male, aged twenty-five years, entered sanatorium January 28, 1925. Both family and past histories were unimportant. He had gonorrhea in 1920; denied having had a chancre.

His present illness began with pain in the left arm in May, 1924. In August of the same year he noticed that his left arm and shoulder were smaller than the right. He consulted a physician but refused spinal puncture at that time. There was a remission of symptoms at this time for a month's duration, then the symptoms returned, and the arm and shoulder became progressively weaker and more painful.

Neurological examination: Romberg negative; pupils equal, regular in outline, reacting to light and accommodation; speech and gait normal; cranial nerves intact, no tremors, slight incoordination of left upper extremity; deep reflexes, diminished left biceps and extensor, otherwise negative; grip diminished in left hand; sensation normal; superficial reflexes present; circulatory, respiratory and gastrointestinal systems negative.

Laboratory reports: Urine negative; blood Wassermann negative; spinal fluid, cell count 12, globulin 18 mgms. to one hundred c. c., sugar 60 mgms. to one hundred c. c., Wassermann four plus in .6 and .8 c. c. dilution in Kolmer and cholesterinized antigens; negative in Noguchi antigen; colloidal gold curve 001130000.

Spinal fluid report: After one month's treatment cell count was 5, globulin 16 mgms. to one hundred c. c., sugar 65 mgms. to one hundred c. c., Wassermann negative in all antigens; colloidal gold curve 0000000000. After six weeks' treatment, cell count 15, globulin 12 mgms. to one hundred c. c., sugar 60 mgms. to one hundred c. c., Wassermann negative in all antigens; colloidal gold curve 0000000000.

CONCLUSIONS

1. Neoarsphenamine combined with spinal drainage and reinforced with mercury both intraspinally and intravenously gives satisfactory results in the treatment of neurosyphilis.

2. When cases do not respond to neoarsphenamine or salvarsan, they often will respond satisfactorily to weekly intramuscular injections of potassium bismuth tartrate with butyn.

3. We have no set rule as to how much treatment should be given nor is any one specific drug used, and an attempt should be made to adapt the treatment to the needs of the patient until a negative spinal fluid Wassermann is obtained.

4. When a negative spinal fluid Wassermann is obtained, no case of neurosyphilis should be dismissed as cured. The necessity of further observation should be impressed upon the patient, also analysis of spinal fluid at three and six month intervals after cessation of active treatment.

5. Dread of spinal puncture is reduced to a minimum in these cases by using a small calibre needle and thoroughly anesthetizing with four per cent novocaine solution.

Pruritus Ani—Its Etiology, Diagnosis and Treatment

CHARLES GOLDMAN, M.D.

Brooklyn

Pruritus ani is not a disease but a most annoying symptom. It is a painful itching about the anus, and it has no established pathology. It is by no means a trivial complaint. The itching, often so intense as to be unbearable, sometimes causes insomnia and a breakdown in the health of the sufferer.

The etiological factors in pruritus ani are as numerous as the remedies suggested for its relief. Any disease of the rectum and anus may be accompanied by itching about the anal region. The most frequent local conditions which may cause pruritis ani are fissures, fistulæ, cryptitis, hypertrophied papillæ, proctitis, anal ulcers, and hemorrhoids. So frequently does itching accompany hemorrhoids that the laity have named the condition itching piles. The itching caused by hemorrhoids, however, is usually not severe.

Moist eczema, eczema marginatum of the anus, herpes, and erythema may be accompanied by pruritus ani. Pruritus ani may be caused by parasites such as pediculi, oxyuris vermicularis (threadworms), acarus scabiei (itchmite), or trichophyton (ringworm). Among diseases which may cause itching of the anus are glycosuria, diabetes, gout, rheumatism, uricacidemia, nephritis, syphilis, and hysteria. Stone in the bladder, chronic prostatitis, vesiculitis, cystitis, and urethritis may cause, reflexly, itching about the anus.

Toxemias of intestinal origin or anaphylaxis following the ingestion of certain foods may be accompanied by pruritus. It is commonly known that shellfish and strawberries are foods which frequently cause severe attacks of itching. Alcoholic drinks, excessive smoking, the use of tea, coffee, and condiments may cause this symptom.

Woolen clothing and clothing colored with poor dyes, or clothing which fits too snugly, or clothing which is so warm that it produces excessive sweating may be the cause of anal itching. Pruritus may be due to the use of irritating soaps, or antiseptics around the anus. There are a limited number of cases of pruritus ani in which it has been absolutely impossible to discover the etiological factor.

In certain patients who have suffered from pruritus ani for a long time there are abnormal conditions of the anal skin such as rugæ, thickening and marked pigmentation, which are undoubtedly secondary to the scratching.

Kiger, of Los Angeles, published a paper in 1918 in which he contended that at least some cases of pruritus ani were caused by infection in distant parts of the body; an infected focus, such as an alveolar

abscess; tonsillitis, frontal sinusitis, chronic appendicitis, or cholecystitis.

Terrell (1) expressed the opinion that the pathology of pruritus ani, with probably few exceptions, is to be looked for in the lowest inch of the alimentary tract.

Dwight H. Murray, of Syracuse, put forward the theory that in his opinion the vast majority of cases of pruritus ani were due to a chronic streptococcus infection. He asserted that a treatment which did not raise the phagocytic power of the blood could have no lasting benefit.

Frick (2) agrees with Murray that pruritus ani is a disease entity, that the constantly recurring Streptococcus fæcalis is the causative factor, that the local pathology is a low grade inflammation, that a cure results from an improved phagocytic power of the blood, and that recurrence will take place if this phagocytic power is reduced. He says, "The vaccine therapy of this disease is established in the fact that the disease is an infection in the deeper layers of the perianal skin and due to a specific organism, the streptococcus fecalis." He reports thirty-nine cases with twenty-seven cures by vaccine therapy.

Montague, of New York, read a paper at a recent meeting of the American Proctologic Society on Vaccines in the Treatment of Pruritus Ani, in which he says that bacterial infection in a pruritic area is likely to occur in all cases. The reason that it does not occur in all cases is due to resistance of normal skin and mucosa to invasion, or to the efficacy of the immune powers of the body cells and plasma fluid to resist such invasion.

The diagnosis of this condition is as easy as its etiology is obscure. The patient comes to the physician complaining of itching around the anus, more severe at night, not relieved, but usually increased by scratching. The patient sometimes gets periods of freedom from the irritation. In cases of long standing the skin around the anus is discolored, and cracked, loses its elasticity, and becomes leathery. Small areas are usually denuded of epithelium by scratching.

All patients suffering from pruritus ani should be given a general as well as a local examination. If the cause can be determined treatment should be directed to removing it. If a constitutional disease exists it should be treated while local treatment is instituted. All local pathology, such as ulcers, fissures, and hemorrhoids, should receive attention. Diseases of the skin should be treated, parasites removed, and the diet, clothing, and the general hygiene supervised. In the presence of local infection an autogenous vaccine should be made, and large doses administered to the patient.

Almost every drug in the pharmacopœia has been used in the treatment of pruritus ani. An excellent palliative measure is the use of green soap locally to clean the region, followed by the application of dilute alcohol. Compresses or enemata of water as hot as can be borne sometimes give temporary relief. Dilatation of the sphincter, the Paquelin cautery, and curetting the parts have met with indifferent success.

Jerome M. Lynch (3) cites a case of pruritus ani of long standing, in which every conceivable remedy had been tried with very little encouragement, but which was cured by x ray treatments.

Rolfe (4) says that he has had great success in the treatment of pruritus ani with ionic medication using a two per cent. solution of zinc chloride.

Where every means of relief has failed we have recourse to surgery. J. P. Lockhart Mummery (5) says that when the itching was of recent origin the removal of the cause was followed by prompt and permanent relief of irritation. In cases of long standing, however, and in severe cases of pruritus ani an actual disease of the nerve endings in the skin existed. This change was realized first by Sir Charles Ball, who had insisted on the fact that a definite nerve lesión was the underlying cause in such cases.

Sir Charles Ball has devised an operation, which he does under general anesthesia, but which may be done under local, in which he divides all the sensory nerve filaments supplying the skin surrounding the anus. This operation by dividing all the sensory branches supplying the skin of this area renders this region superficially anesthetic, and relieves all itching. Though there may be a recurrence of the itching it is not likely to occur for two or three years.

The modified technic of Ball's operation as done under local anesthesia is as follows: The patient is given a hyperdermic injection of morphine sulphate one quarter grain and hyoscine one one hundred and fiftieth grain, and is placed on his left side with his knees and thighs flexed. The area surrounding the anus is cleansed, shaved, and sterilized. At two points about one-eighth of one per cent. betaeucaine lactate is injected, taking in an area extending to the anterior and to the posterior midlines. A blunt pointed dissecting scissors is introduced through small incisions made at the points of injection, and the skin dissected mesially and to the raphés anteriorly and posteriorly. The bleeding is controlled by pressure. The wound heals in two or three days. The patient is kept on an absorbable liquid diet, and the bowels are opened with an enema on the fourth day. Where the results of the operation are not satisfactory some of the sensory nerves have been missed in dissecting.

Nitritoid Crises Following Bismuth Injections.—C. Simon (*Bulletin Médical,* September 24 and 27, 1924) calls attention to the fact that even intramuscular injections of an insoluble bismuth salt may give rise to nitritoid crises similar to those following intravenous injection of arsphenamine, with sudden flushing of the face, conjunctival congestion, general discomfort and a bounding pulse. None of his six cases, however, showed subsequent vomiting or syncopal pallor. The crises occurred immediately after properly performed intramuscular injections, with all customary precautions taken to obviate entrance of the drug into a vein. In no case did the crisis follow the initial injection of bismuth.

The Treatment of Acne by the Combined Use of the X Ray and the Mercury Quartz Light

EUGENE F. TRAUB, M.D.
New York

The object of this paper is to present a method of treating acne vulgaris, which in my hands has given most gratifying results.

General hygienic measures, such as diet, the correction of constipation, and pelvic abnormalities, must of course be taken care of, as in every other method. The patient is given directions as to diet with an instruction sheet and list of foods. He is directed to check off on the food list the various items eaten during the course of the week. On the next visit this diet list is reviewed with the patient, and errors in selection are corrected.

General instructions.—Eat no sweets or fried or greasy foods; eat slowly and at regular intervals; avoid eating when fatigued or in a nervous condition; eat freely of laxative foods, especially bran; drink plenty of water between meals; do a number of bending exercises every night and morning to strengthen the abdominal muscles; establish regularity in living habits.

Special instruction.—Mineral oil, with or without agar agar in tablespoonful doses three times a day before meals in those cases where constipation is apparently a factor. This is discontinued as soon as possible. Bacillus acidophilus milk or tablets are of value in obstinate cases. The face is to be thoroughly washed with soap and lukewarm water, using a rubber sponge and tincture of green soap, at least twice a day, rinsing with ice cold water. Never use hot water.

At the first visit the patient's attention should be called to any scarring or pitting that may be present, as this is often overlooked in the presence of more conspicuous pustules and comedones. On the disappearance of the latter in the course of the treatment, the scars become correspondingly more noticeable, since the lesions present at the beginning have increased their number. Although the irradiation is not responsible for the scarring it occasionally seems to make it more pronounced, which perhaps may be accounted for by the alteration in the skin of gland function and the reproductive ability of the follicular epidermis. The patient should be warned of the possibility of a temporary pigmentation which may occasionally persist for some months. In blonds this manifests itself in the form of freckles, whereas in brunettes it is usually more diffuse.

The very mild cases of acne are not usually treated with the x rays. It has been my routine to select only the more severe and obstinate ones, assuming that in these the x ray is unquestionably the method of choice. The patient is advised that a number of treatments at weekly intervals will be required and that it is useless to begin with the idea of "trying a few treatments to see if any improvement takes place." Flareups occurring during the first few weeks of x ray treatment are not uncommon. In some cases no improvement is noted until the patient has been irradiated eight or more times. Progress during this interval is generally facilitated by the removal of the comedones and opening and drainage of the pustules and abscesses present. If carefully and regularly done this minimizes the scarring and fewer lesions are present after each visit much to the patient's satisfaction.

I have considered the patient to have sufficient x ray treatment when all the lesions have disappeared and no new ones have been noted for a period of about two to three weeks. In other words, the patient is given two or three additional treatments to insure a more permanent result. The routine course consists of twelve to twenty exposures at weekly intervals, the average being fifteen. The dose is one eighth skin unit centre and one quarter skin unit on each side (Witherbee and Remer (1) unit) using the factors 3 mil. 6 in. spark gap, 8 in. dist. 15″-30″ time respectively.

One week after the last x ray exposure the patient is given a prolonged exposure with a mercury quartz light. Any mercury quartz light—Alpine sun, Burdick or Kromayer light—may be used for this purpose and they will be referred to as the mercury light. Sufficient dose is given to produce what would correspond to a second degree reaction from the sun, and daily applications of boric acid solution are advised. Two weeks are allowed to elapse and this exposure is repeated. If there is any scarring or any evidence of a dry or wrinkled skin, or pigmentation, a third mercury light treatment is given from two to four weeks after the second. It is essential to peel the skin thoroughly. In mild cases of acne, the mercury light used in conjunction with the x ray or lotions is often extremely successful. But in the more severe cases the mercury light is used at the conclusion of the x ray course to peel the dry and wrinkled skin and to flatten out and efface the scarring.

This may also do away with any possible future untoward x ray sequelæ. Its value to prevent x ray burns has already been recognized (Sampson (2). If employed directly before x ray treatment is begun or during a course of treatment, a decided tanning occasionally becomes apparent. However, in spite of this, if there are great numbers of superficial comedones the treatment may be shortened by giving a mercury light peeling in the midst of the x ray course, remembering the temporary pigmentation which may ensue. If any mild superficial pustulation occurs on the new, tender and susceptible skin (post desquamation), this may be controlled with a boric acid wet dressing or a mild lotio alba.

As intimated, in mild cases the x ray and mercury light have been used alternately as follows: one quarter skin unit at the first visit; the next week a mercury light exposure of just sufficient dosage to produce a very faint erythema. The following week the quarter unit x ray is repeated and so these two therapeutic agents are alternated to the completion

of the course. This usually averages twelve x ray treatments or less. The slight disadvantage of this procedure is that the length of the total series is almost doubled.

One hundred and thirty-four patients were treated with x ray alone between July 1, 1922, to July 1, 1923. Ninety-nine of these patients were given over ten treatments, whereas the remaining thirty-five received less than ten. Undoubtedly only a small number, if any of those in the latter group were improved or cured.

A small number of patients in the former group of cases who had excessive numbers of comedones and pustules were not greatly improved by the time the fifteenth dose was reached and consequently discontinued treatment. However, the majority of the cases in this group were discharged cured. An effort is now being made to get late figures on the outcome of these and previously treated cases with a view to tabulating comparative results of x ray cases and those treated by the combined method as above outlined.

During the same period thirty-six patients were treated by the x ray mercury light and the removal of blackheads. But one patient so managed has had any return of acne to date and in this case only twelve x ray doses were given. The average number of x ray exposures required in cases treated by the combined method has been considerably less than in those where the x ray alone was employed.

SUMMARY AND CONCLUSIONS

X ray treatment, which is the conceded method of choice in the more severe cases of acne, is advantageously supplemented by the regular and careful removal of all comedones and the drainage of all deep pustules and abscesses. This greatly reduces the amout of scarring which would otherwise result were the x rays employed alone. The artificial sunburn following the course reduces greatly that scarring which is unavoidably present, peels off the dry and wrinkled skin, effaces any pigmentation, and probably lessens the danger of any x ray sequelæ. A patient so treated and examined later shows no sign of ever having had x ray treatments. By alternating one quarter unit x ray with mercury light treatments at weekly intervals all danger of a radio dermatitis is eliminated and the end result is most gratifying.

Parasitic Eczema

RUDOLPH BOENKE, Ph.G., M.D.

Long Island City, N. Y.

In years past eczema of a type resistant to the ordinary treatment for eczema, and occurring most commonly on the hands and feet, was looked upon as being probably caused by an infectious organism and was therefore called parasitic eczema.

Hebra in 1860 first called attention to the fact that the disease called eczema marginatum was caused by a form of tinea. In 1892 Mouktar described the disease as it occurred on the hands and feet, and it was again described in 1908 by Whitfield. In 1910 Sabouraud demonstrated that the organism producing eczema marginatum was the same as that producing parasitic eczema on the hands and feet. In 1916, Mitchell and Ormsby reviewed the literature, described the clinical types of the disorder and published the results of cultures obtained from seventeen cases, identifying the Epidermophyton inguinale. In 1921, Mitchell of Chicago again published a report of further cultural studies of the Epidermophyton inguinale in which the organism was recovered from a number of cases: he also describes a white organism growing in pure cultures from specimens taken from some of his patients, but which he was unable to identify. This same organism had previously been grown and the cultural characteristics described by Kauffmann-Wolff who also had been unable to identify it.

Clinically there are several types of the disease. Tinea cruris, or eczema marginatum, as we usually see it, involves the perineum and the adjacent part of the thighs, being bilateral due to the apposition of the opposing surfaces; in long standing cases the lesion may extend upward onto the pubic region, outward on the groins and downward along the inner part of the thighs toward the knees; occasionally a single patch may be found on the inner aspect of either thigh. The lesions have sharply demarcated borders, the inflammation not gradually shading off into the surrounding skin but ending abruptly. The advancing border is raised, is slightly scaly and usually of a deep red color; the central portion may have the same deep red color or may be of a lighter shade. It is increased by heat and moisture which are commonly present in those parts of the body affected, that is, where skin surfaces are apposed, as the perineal region, the axillæ and under the breasts of women; it is also sometimes found on the buttocks, and about the umbilicus. Subjective sensations are itching or burning.

On the hands and feet the most common type of epidermophytosis we see is a chronic circumscribed patch or patches of eczemalike eruption, more or less red, studded with vesicles of various sizes which are comparatively superficial, some desquamation, but, in contradistinction to simple eczema, having a sharply defined border; the inflammation does not shade off into the surrounding skin. It usually begins as a small, inflamed, and vesicular spot, the

vesicles rupture, become dry, and desquamation takes place at the site of the vesicles, while new vesicles arise at the margins of the patch; as the lesion extends fresh crops of vesicles keep on forming in the area previously affected. It is usually found on the backs of the hands and along the fingers but it also occurs on the palms, on the forearms and may occur on other parts of the glabrous skin, but always in circumscribed patches; there may be only a single patch but usually there are two or more patches of various sizes.

On the feet the lesions may be similar to those found on the hands, but more often it is confined to the toes, chiefly affecting the third and fourth interspaces and the contiguous parts of the dorsal and plantar surfaces; here, due to the approximation of the toes, the epithelium is often found in a macerated and sodden condition, and in places the skin is denuded of its epithelial layer; these denuded areas are of an inflammatory red color and appear shiny and dry, while at the border of the lesion small superficial vesicles may be seen. Fissures may also be present. On the plantar surface, due to the thicker horny layer, the vesicles appear more deeply seated and do not rupture as quickly as when situated in the softer skin, but when ruptured, dry quickly. Some vesicles do not rupture but seem to become absorbed and leave a small brownish dot which is followed by desquamation; scaly patches are thus formed in which new vesicles arise; at or beyond the border vesicles also develop causing an extension of the process. Mouktar, in his report published in 1892, described a case in which there was present only an excessive amount of callus on the soles, from which he had recovered the tinea fungus. On the dorsal surface of the foot and on the legs the lesions resemble those found on the hands and forearms.

In tabulating a series of 238 cases that were clinically epidermophytosis 118 cases occurred in males and 120 in females, showing that the disease is equally prevalent in both sexes. The age ranged from two to sixty-three years with the majority of cases occurring between eighteen to thirty-five years. This shows that age is not a factor; it occurs at almost all ages. Occupation seems to play an important rôle in the incidence of the disease, by far the greatest number of cases occurring in those who find it necessary to use water to a great extent in their work. When one remembers that the organism or fungus thrives in the presence of heat and moisture one can easily understand why this is so. The following is a list of percentage of the occupations:

Occupation	*Percentage*
Housework	37
Restaurant workers (including cooks, dishwashers, waiters and waitresses)	14
Clerk, tailors, barbers, each	5
Operators	5
Laborers, cutters, each	3
Pedlar, stenographer, watchman, porter, student, dressmaker, storekeeper, each	2
Cigarmaker, ironworker, embroidery, showcases, sailor, elevator man, electrician, orderly, sheetmetal worker, each	1

This shows that over fifty per cent. of the cases occur in persons compelled by their occupation to use water extensively, while twelve per cent. of the remainder, that is, the tailors and barbers, also use considerable water in the course of their work. Locations of the lesions would also indicate that the occupation is a predisposing factor in the locations affected:

Location	*Percentage*
Both hands	39
One hand	15
Toes	13
Fingers	11
One foot	5
Both feet	3
Forearms and thighs	3
One forearm	5
Hands and arms	2
Both hands and feet	1
Feet and knees	1
Fingers and toes	1
Scrotum	1

When we come to analyze this, we find that seventy-seven per cent. of the patients had lesions on the hands and forearms, that is, infection of that part of the body most exposed to traumatism and infection by reason of manual labor. We also find that in twenty-six per cent. the infection was unilateral: while this percentage may seem high in an infectious skin disease where there is every opportunity for autoinoculation to take place through daily contact, many patients give a history of the lesion appearing first on one side, and then some time later appearing on the other: we must assume, therefore, that in many of the unilateral cases sufficient time had not yet elapsed for autoinoculation to take place. Mitchell, in his paper in 1921, cites an instance of conjugal infection in which a recently married man brought his bride for examination for a condition of the hands and feet which had arisen shortly after marriage, and which he feared he might contract. Examination of the husband showed the typical maceration and fissures about the toes of long standing, and on being questioned he recalled having had eczema marginatum during his college days.

Beside personal contact, the disease may be transmitted through the use of improperly laundered towels in public baths, or walking barefoot in such places, as the infective organism may be deposited on the floors or on towels by persons already infected. It may be transmitted from one member of a family to the others by the same means, or by wearing the slippers of an infected relative.

The cases of tinea cruris or eczema marginatum that occurred during the same period as the epidermophytosis were not included in the list before mentioned: there were only nine cases showing it to be of comparatively infrequent occurrence as compared with infection of the extremities. There were eight males and one female; this preponderance in males I believe is due to the fact that many men are accustomed to wearing heavy woolen undergarments which cause more or less perspiration of the crural region and so produce favorable conditions for the growth of the organism. The ages ranged between twenty-six and sixty years, none occurring in children. Occupation did not seem to be an important factor; while no two had the same occupation, the majority were men more or less with outdoor occupations and therefore accustomed to dressing warmly; yet from these few cases one is not justified in drawing conclusions:

Location	Percentage
Scrotum and thighs	2
Both thighs	2
Scrotum and crural region	1
Scrotum alone	1
Thighs and buttocks	1
Thigh, one only	2

In only two of the nine cases the thighs were not affected. The duration ranged from one week in an acute case to three years in a chronic one.

TREATMENT

At the present time much reliance is placed in Whitfield's ointment which is composed of salicylic and benzoic acids in an ointment base; if used in sufficient strength, the epidermis is exfoliated by the salicylic acids when both acids act as fungicides. This ointment usually produces beneficial results but is not always curative.

In the cases which are very resistant to treatment repeated exposures to fractional doses of x rays usually bring about a cure.

Other remedies that have been found to be useful are chrysarobin in ointment up to ten per cent., and a saturated solution of silver nitrate in alcohol or sweet spirit of nitre.

Rhus Dermatitis: Its Treatment With Poison Ivy Extract*

RALPH OAKLEY CLOCK, M.D., F.A.C.P.
Pearl River, N. Y.

Everyone is to some degree susceptible to poison ivy. However, there seems to be little foundation for the statement that rhus dermatitis may develop in persons who merely walk past the plant. Actual contact with the resinous sap of the plant is necessary to produce rhus dermatitis, but this contact may be brought about through an intermediary agent which carries the sap, such as particles of soot in smoke from the burning plants, as well as clothing long after contact with the plant.

The work of Strickler established a scientific basis for the treatment of rhus dermatitis by injection of poison ivy extracts. Several workers have obtained clinical cures with his alcoholic extract when injected intramuscularly, but many patients have complained that injection of the extract caused severe pain. Undoubtedly, this pain was due to the high percentage of alcohol used to hold the active principle in solution.

ALMOND OIL EXTRACT

Our laboratory studies, which have been carried out during the past three years on the subject of poison ivy (rhus toxicodendron), have included the problem of supplying the active principle in correct therapeutic doses in a solution that would permit of its being injected without the pain caused by the alcohol. As a result of these investigations, a solution of the purified active principle in almond oil has been prepared.

LABORATORY TESTS

Repeated tests of this product on laboratory animals have shown it to be nontoxic, and clinical trials have demonstrated its efficiency. This extract possesses the advantage of being nonirritating and its injection, therefore, does not cause severe reactions or pain. Moreover, since the oil is slowly absorbed from the tissues, a larger amount of the active principle can be used in each dose. Immunological tests indicate that this almond oil extract is more potent than any extract of poison ivy that has thus far been prepared.

*Read at the joint meeting of the Bergen County, N. J., and Rockland County, N. Y., Medical Societies, held at Pearl River, N. Y., May 20, 1925.

CAUTION

Care should be exercised when injecting the almond oil extract of poison ivy for, if the extract is inadvertently dropped on the skin, it may cause typical rhus dermatitis. In order to guard against this possibility and, at the same time, to relieve the physician of the necessity for cleaning his own syringe, the almond oil extract is furnished in syringes which may be destroyed after use. When stored in a cool place, the oily base becomes more viscid, thus making it difficult to inject the extract through the needle. For this reason it is important to warm the extract (not above body temperature) before using.

DOSE AND ADMINISTRATION

As a rule one injection of one c. c. of the almond oil extract will be found to give relief. In severe cases two or three doses may be required at intervals of twenty-four hours. Usually the subjective symptoms of itching are relieved in twelve to twenty-four hours after the first dose, and local reactions are absent. When administering the almond oil extract it is important to make all injections intramuscularly and not subcutaneously. The best location for the injection is in the deltoid muscle, just below the point of the shoulder.

Some three hundred drugs and chemicals have been studied as local remedies for ivy poisoning, and it has been suggested that it would prove beneficial to remove that portion of the poison that has not penetrated or combined with the skin by the use of a solvent and precipitant combined, such as two per cent. alcoholic solution of lead acetate. However, any local treatment is relatively ineffective when compared with the results that have been obtained by the intramuscular injection of the almond oil extract of poison ivy.

CLINICAL REPORTS

In order to demonstrate the practical value of this extract I shall present excerpts from two or three clinical reports received from various parts of the country.

New York: "Prompt and complete cessation of

itching within six to twelve hours after the administration of the first dose."

New Jersey: "Face and hands involved. Two doses given. No improvement after first dose, but condition was arrested. Improvement prompt after second dose. No local reaction occurred from either dose. This case was one of extreme susceptibility to poison ivy. Last year the patient was given three injections of a poison ivy extract in alcoholic solution for treatment. Was benefited at that time, but painful local reactions followed and patient did not want injections this year until assured that injections of poison ivy extract in almond oil would not cause so severe pain. Patient was very much pleased with contrast in local reactions of injections."

Virginia: "Two doses given. Improvement followed first dose. No local reaction. Patient entirely satisfied and relieved."

Alabama: "I will say that I find the poison ivy extract in almond oil far less irritating than the antigen preparation (alcoholic extract) which has heretofore been used, and have found your preparation to come up to the fullest expectations. In each case I have stated to the patient that within twenty-four hours after first dose they could notice that the itching, etc., would stop, though the course would be from two to three doses twenty-four hours apart. They have voluntarily stated that the first dose acted as specifically as stated to them."

SUMMARY AND CONCLUSIONS

The important points which I think warrant emphasis are as follows:

1. All persons are susceptible in some degree to poison ivy.
2. Actual contact with the sap of the plant is necessary to produce rhus dermatitis, but such contact may result through some intermediary agent which carries the sap.
3. Alcoholic extracts of poison ivy cause painful local reactions, which are undoubtedly due to the high percentage of alcohol used to hold the active principle in solution.
4. Poison ivy extract in almond oil contains the purified active principle of rhus toxicodendron, freed from coloring matter and inert water soluble substances.
5. Laboratory tests have shown that the almond oil extract is nontoxic and more potent than any other extract of poison ivy thus far prepared.
6. Poison ivy extract in almond oil can be injected without pain or local reaction. It should be administered intramuscularly, preferably in the deltoid muscle just below the point of the shoulder.
7. Clinical reports from several states indicate that prompt relief usually follows in twelve to twenty-four hours after the first dose of poison ivy extract in almond oil. Severe cases require two or three doses.

Causes of Severe Syphilitic Lesions

JOSEPH WITTENBERG, M.D.
Brooklyn

Every syphilologist of experience meets patients in whom treatment for syphilis appears to be ineffective. The unfavorable results are of several types, some fairly common, others less so and some quite rare. From a large amount of clinical material I have, during the past year, separated groups which give clinically different types of unfavorable results. This paper is a study of some of the causes of these results. It also considers any modification of treatment the study suggests.

Types of unfavorable results encountered were: Persistence of lesions in spite of treatment; recurrence of lesions in spite of treatment; phenomena of increased severity following treatment; appearance of precocious lesions, usually in patients that had been treated energetically; occurrence of destructive lesions in spite of energetic treatment.

To understand the reasons for these untoward effects it is necessary, first, to review some of the pathological changes produced in the body by the spirochetal infection—the reaction between the spirochetes and their products and the tissue cells as far as they are known; also the modifications of these produced by treatment. The known facts may then be used as guide posts to a further study of the subject; and one may attempt to fill any hiatuses left to a complete understanding of the process of damage and healing with reactions familiar in medicine which will dovetail into these hiatuses.

The reaction of the tissues to the Spirochæta pallida is multiple and may be divided into specific and nonspecific. The specific reactions include production of antibody, which presumably gives the Wassermann reaction; the nonspecific reactions include production of the lesions and their healing.

The antibody of syphilis is produced when and where the reacting cells are exposed to irritation by the spirochetal endotoxin. A proof of this is that serum taken from the chancre gives positive serological findings early, while the blood is still negative. That the production of this antibody is due to the toxin rather than to the spirochete itself is proved by the provocative test. This test consists of the administration of a strong spirochetecide. If spirochetes are present in the body they are destroyed, their endotoxin is liberated and a previously negative Wassermann reaction is changed to a positive one.

It seems that the specific antibody is thrown into the blood at its point of production and quickly becomes diluted. The tests known to us at present show the presence of this substance only when above a certain concentration; so that we may have a good local reaction, as at the chancre or other active lesion, yet have a negative Wassermann.

The phenomena of increased severity is a condition where lesions of unusual severity occur in syphilis and is admittedly due to improper treatment.

It was and is yet quite commonly alleged to be due to "inadequate intensive treatment, and that a few doses of arsphenamine, without continued treatment, may result in more severe manifestations than if milder therapy had been applied" (1).

I wish to point out here that this opinion is erroneous; that the increased severity of the lesions is not due to too few injections of arsphenamine but to too many for that particular patient.

I quoted from a previous article (2). "The explanation given (for the appearance of the phenomena of increased severity) is that the arsphemanine destroys the spirochetes so rapidly that there is no time for the tissues to become acclimatized to the irritation by the germs; and a small focus of spirochetes tucked away safely from the action of the arsenic, somewhere in the tissues, develops in the susceptible host with great rapidity and severity—I repeat, this occurs because "the tissues have not become acclimatized to the germs."

That this reasoning is unsatisfactory is seen at once when we consider that the body was certainly unacclimatized to the spirochetes before the infection; so that increased severity necessarily means that the resistance is less in that patient than in one who had not been treated with arsphenamine; that the resistance has been lowered; that the antibody producing cells or tissues (and other resisting cells) have been damaged. This to me seems selfevident and needs no further proof.

In order to understand the reason for the persistence of lesions beyond the normal, for exceptionally severe lesions, for precocious lesions, etc., we must study the normal mechanism of lesion production in syphilis.

Why does the chancre show marked differences from later lesions? and why do secondary lesions show gross differences from the tertiary though microscopically similar?

What different conditions obtain in the body when the chancre is formed from those present when the secondaries appear? When the chancre is developing there is no general systemic reaction, no positive Wassermann. The chancre is the local reaction to the presence of the spirochetes; the struggle between the irritants and the defending cells is a prolonged one and a comparatively large, massive infiltration results. The secondary lesions are, as a rule, smaller and slighter; here have been no such well matched antagonists as at the production of the primary sore. Why? We can easily imagine that specific antibody which has been formed in the meantime, plays a part antagonistic to the organisms so that a lesser local reaction is sufficient to destroy or control them here than is needed in the chancre.

If we were asked to give in a few words the outstanding differences between the individual secondary and tertiary lesions, we would say the tertiary lesions are larger though they contain few spirochetes. Why this difference? A study of certain characteristics of the delayed roseola may help to a solution of the problem.

The delayed roseola is distinguished from the ordinary roseola in this wise. Here and there a macule is found with a border that is sharply defined, instead of gradually fading into the healthy skin. What is the reason for this sharp margin?

If these lesions were produced by the destruction of the tissue cells as a result of the presence of the spirochetes we would say that the resistance of the cells is great, greater in the delayed roseola than is usual, and this resistance is finally overcome by the great mass of spirochetes in the centre of their camp, while the lesser number of organisms on the outskirts are successfully resisted; so that the lesser reaction seen at the border of the ordinary macule is missing. We know, however, that the contrary is true; it is liberation of endotoxin due to destruction of the spirochetes that produces the lesions. This is shown, in an exaggerated form, by the Herxheimer reaction.

We thus see that while a more or less thickly grouped mass of spirochetes are destroyed by the defending cells, spirochetes in a lesser concentration are not. Evidently a lack of attraction (perhaps due to a low content of specific opsonins) exists. The theoretical negative chemotaxis between phagocytic cells and microorganisms which was once taught would have explained this phenomenon well.

This lack of attraction, whatever the cause, is unduly prolonged in the delayed roseola and is finally overcome at a high threshold. The fewer organisms at the periphery of the camp of spirochetes are not destroyed and the usual areola at the border of the macule is missing.

The question rises here, why do not all the macules of the delayed roseola show the same characteristics? Perhaps the slight increase of endotoxin produced at the sharply defined macules results in an increase of antibody, sufficient to help overcome the resistance between the tissue cells and the spirochetes; perhaps, in most of the macules, the destruction of the spirochetes in the centre of the camp is accompanied by an overflow of endotoxins into the tissue about it, and the irritation by this, either by stimulating the tissue cells or weakening the spirochetes or both is sufficient to overcome the lack of attraction between the tissue cells and the spirochetes.

In the animal economy stimulation of a function by any substance can be carried to a point beyond which depression sets in; and with continued dosing with the drug or toxin the depression becomes intense. In syphilis the lack of attraction between the tissue cells and the spirochetes is first intensified then lessened and abolished, and where the presence of many spirochetes resulted formerly in slight lesions, a few now produce severe ones.

I say the lack of attraction is first intensified for the following reason. In presalvarsan days a common form of treatment, the administration of mercury by the mouth, was often insufficient to prevent the appearance of the roseola but was effective in delaying it.

In the average case of syphilis the increased susceptibility of the tissue cells appears late. In exceptional instances this appears sooner, whether from an unusually virulent infection or an unusual sensitiveness of the resisting cells.

With exhibition of medication that intensifies these actions though still insufficient to destroy all the spirochetes, the normal processes are exaggerated. And when the medication is carried beyond the optimum for the particular patient we get first, persistance or recurrence of the lesions; at a more ad-

vanced stage of overstimulation, the phenomena of increased severity; and at a still more advanced stage, precocious lesions.

We know of three actions of antiluetic remedies: 1, Absorption of syphilitic infiltration; 2, spirocheticidal action; 3, action on production of antibody.

We know from of old that potassium iodide is effective in the absorption of syphilitic granuloma, though its mode of action is still somewhat doubtful. As a spirochetecide it is of little if any value (3).

We may therefore expect potassium iodide to relieve such symptoms and signs as are caused by the presence (mechanically) of luetic infiltration. It may aid spirocheticidal action by uncovering such of the organisms as are buried in the luetic infiltrate. To expect relief of symptoms due to the syphilitic infiltration is therefore logical, to hope for a reversal of a positive Wassermann by administration of iodides is not, and clinical results bear this out.

We know, clinically, that arsphenamine is also very active in causing absorption of syphilitic granulation tissue. And this is not due, merely, to destruction of spirochetes because the tertiary lesions contain but few of these organisms, yet they respond to the arsenic well.

Arsphenamine and mercury, as well as bismuth, are spirocheticides. In what form these drugs act is uncertain. Arsphenamine will destroy the spirochetes in a test tube in a solution of one to one thousand; when the arsenic is digested with protein it is thirty to forty times as powerful (3). That one injection of arsphenamine as a rule destroys the spirochetes in active lesions is readily seen by examining juice squeezed from the chancre before the injection and the day after. Mercury is also spirocheticidal, but much less so than the arsenic, and bismuth seems to come in somewhere between the two.

In time, the spirocheticidal action of the drugs becomes weakened *in vitro* and *in vivo*. Akatsu and Noguchi showed that the Spirochæta pallida increase in tolerance to salvarsan five and a half times in three to four months in the test tube, and to bichloride, thirty-five to seventy times (4).

We have seen that antibody is produced in response to irritation by the spirochetal endotoxins. The clinical significance of the presence or absence of a positive Wassermann reaction in the syphilitic at different times is more difficult to explain. We know: 1, That spirocheticides injected into nonluetics will not produce antibody (a positive Wassermann); 2, the use of spirocheticides continued in a person after he is cured of syphilis will not keep the Wassermann reaction positive; 3, the Wassermann reaction may continue negative for a long period and then active symptoms reappear with a positive Wassermann; 4, it is common knowledge that the Wassermann reaction is sometimes negative though the patient presents active lesions, like a florid syphilide.

The explanation for the appearance of the untoward lesions and the variations in the Wassermann reaction becomes simple when we consider the numerous factors that may enter into the picture complex of syphilis at any one time. These factors (which have been analyzed above) include a, the local reaction between the tissues and the spirochetes; b, those connected with the production of antibody; c, the reaction to the drugs used.

The spirochetes may attack at one time any part or parts of the body; different tissues or groups of tissues are attacked at different times; some tissues are attacked more than once. We must expect that the different types of cells react differently to the spirochetes and to their toxins; and that the resistance of each tissue varies with succeeding attacks. Pearce and Brown have proposed two laws bearing on this matter.

It is safe to assume that the different antibody forming cells are no more uniform in their powers than the different tissues are in their susceptibility to the syphilitic infection; and some are exhausted sooner than others.

We know that the phenomena of increased severity are less apt to appear when mercury is given after the arsphenamine. This shows that the different drugs, arsenic, mercury and no doubt bismuth, each acts differently on the immunity building and the local reacting tissues. It is also quite likely that a type of tissue stimulated strongly by one drug is acted on weakly or perhaps not at all by another.

We can now readily understand how, in certain instances, a florid syphilis is present while the systemic reaction has not as yet progressed to the stage of a positive Wassermann reaction. Here an injection of arsphenamine promptly destroys many spirochetes, a large amount of endotoxin is liberated and thrown into the circulation, the antibody production is stimulated and we get a positive reaction.

Lesions of increased severity mean that the tissues forming the sites of these lesions have been overstimulated. If, at the same time, a large part of the antibody producing cells is in a state of stimulation against the toxins, the Wassermann is positive; if in a state of overstimulation, it is negative.

When the reaction of the tissues to the disease gets beyond a certain point, we must expect that while some tissues may still be stimulated to favorable reaction, others will be distinctly injured by continuance of the same treatment.

The lesson that all this teaches is that the syphilitic patient is not a "case of syphilis" to be treated nor even "a patient with syphilis." He is a human organism who, aside for his mental and emotional characteristics, has a number of organs and tissues, each with certain physiological functions. That these organs and tissues are of different and differing powers of resistance; that they are attacked at different times, many, a varying number of times by the spirochetes and their toxins. With treatment the problem is further complicated by the different actions of the drugs on the different tissues. And when one tissue reacts badly to any drug or measure, even though the rest of the body responds well, that drug or measure must be discontinued or its administration modified.

The syphilologist should hold it as a law in medicine, that with the administration of antisyphilitic treatment, the patient's general health must be looked after. In obstinate or severe cases this may mean the difference between favorable and disastrous results. We see patients in whom persistent and intensive treatment fails to stay the progress of destructive lesions who respond promptly and well to tonic treatment when that is indicated or to care for the gastrointestinal tract and other organs.

The method used by our fathers of stopping all antisyphilitic treatment in patients who were not doing well on such medication and putting them for some time on a tonic laxative preparation like the old Zittman decoction could be used to advantage today in many cases.

SUMMARY

1. In the early stages of syphilis the reaction between the Spirochæta pallida and the defending tissue cells is lack of attraction. With the efforts of Nature to cure the disease and with treatment, this action is first stimulated, then lessened and then abolished. Therefore, while early in the disease many spirochetes produce mild lesions, in the later stages few of the organisms produce severe lesions.

2. Different tissues have different powers of resistance to the syphilitic infection. The resistance of some tissues may have been diminished or overcome while the rest of the body reacts well.

3. Tissues are unequally susceptible to a drug. A dose which acts well on one kind of tissue cell may be too large for another and insufficient for a third.

4. For these reasons a change in the treatment is indicated when any tissue or organ reacts badly to the treatment that is administered.

5. It should be a law in medicine that with the antisyphilitic treatment the general health of the patient should receive proper attention. If in spite of such care and medication the patient does not do well, it is advisable to stop all antisyphilitic remedies for a time, while tonic and symptomatic treatment is given.

Bismuth in Treatment of Syphilis

GEORGE J. MUELLERSCHOEN, M.D.

Philadelphia, Pa.

The spirocheticide properties of bismuth were only established incontestably in 1921 by Sazerac and Levaditi in experiments on animals. Subsequent extensive clinical trials, which have been recorded in numerous articles, soon proved that this discovery was of considerable therapeutic value. Today there is no longer any doubt that the bismuth compounds are a useful adjunct in the treatment of syphilis. They prove useful above all when the organism cannot support the arsenicals or mercury, or when the disease resists these remedies. Besides this, on account of their low toxicity and more intensive action on the spirochetes and in the Wassermann reaction, they may with advantage take the place of mercury compounds in mixed antisyphilis treatments.

So far the bismuth preparations have generally been administered intramuscularly, in the form of insoluble compounds.

The experiments on animals have been chiefly made with soluble bismuth salts—tartrate of bismuth, ammonium tartrate of bismuth, lactate of bismuth (Robert and Sauton; Sazerac and Levaditi; Giemsa), which were injected both subcutaneously and intravenously. Besides these soluble salts, several other bismuth compounds have been reported in literature as, for instance, the bismuth compounds of pyrogallol, of phenol (Grenet and Drouin), bigallate and bioxyiodogallate (Sazerac and Levaditi), bisalicylate, subnitrate, and subcarbonate (Zollinger), the bismuth compounds of thioglycol acid and of thiourea (Ritz), colloidal bismuth and bismuth hydroxide (Zollinger, Fournier and Guenot, and others).

From a toxicological viewpoint, the following conclusions have been established: The toxicity of the bismuth salts depends on the ionizable bismuth: it is greater by intravenous than by subcutaneous injection. Subcutaneously injected bismuth compounds showed varying toxicity, according to the degree of solubility. Certain insoluble bismuth compounds are only very slowly reabsorbed after subcutaneous injection, and form deposits, which on occasion can bring about a sudden bismuth poisoning (Wolfer). Parenterally administered bismuth is for the greater part eliminated in the urine, and only in very small quantities in the stool. It has also been detected in other secretions—gall, saliva, cerebrospinal fluid, and so on (Zollinger, Benech). Elimination of bismuth is slow, especially when preparations which dissolve with difficulty have been administered by subcutaneous injection. After intravenous injection the bismuth is eliminated more rapidly.

From a therapeutic viewpoint all bismuth salts proved to be effective, in proportion to their reabsorption, against poultry spirillose (Robert and Sauton), rabbit syphilis (Sazerac and Levaditi, Giemsa, Ritz). The specific effect on the spirochetes was prophylactic as well as curative in these instances. The results obtained with Nagana infected guinea-pigs are less definite (Sazerac and Levaditi).

The first clinical experiments following the experiments on animals, indicated that bismuth preparations would prove of value in the treatment of human syphilis. Since then the results of numerous investigations have confirmed this view. At the beginning, byeffects were noticed from the bismuth treatment (stomatitis, gingivitis, in a few cases slight albuminuria). As soon as sufficient data became available through systematic research on the use of the preparations and their dose, it was found that these byeffects could be either entirely avoided or at least reduced to a negligible degree.

In the treatment of syphilis with bismuth preparations given orally a few observations soon established the fact that therapeutic possibilities from this method of administration are remote. Treatment by intramuscular injection has proved so far to be the best: for this purpose fine oily suspensions of various bismuth compounds are being used. These preparations represent bismuth in an insoluble form, and when injected absorption takes place very slowly (Sazerac and Levaditi; Fournier and Guenot; Bernard; Emery and Morin; Bloch; Müller; Felke, and others).

Having followed with great interest the reports of various investigators published in foreign literature on the use of bismuth in the treatment of syphilis, we decided to conduct a series of experiments in our clinic. The experiments began in September, 1923. The bismuth preparation we selected for the purpose is an oleate of bismuth in a fine oily suspension, known as oleo-bi. Approximately eight hundred injections have been given to fifty-two patients. Out of this number we have been able to obtain complete records in twenty-seven cases. These patients have for the most part received neither mercury nor iodides, nor any of the arsenicals, in order to make our test of the value of bismuth as conclusive as possible.

In these twenty-seven cases the diagnosis had shown twenty-one secondaries (seventy-eight per cent.) and six latents (twenty-two per cent). Twelve injections were given for a course, at periods one week apart; one ampoul of two c. c. containing 0.10 gm. bismuth, was used for each dose.

Clinical results.—Serological tests at conclusion of the treatments showed negative Wassermann in fifteen (seventy-one per cent.) of the twenty-one secondary cases and in four (sixty-six per cent.) of the six latent cases. In the whole twenty-seven cases in which the treatment was completed there was thus obtained a negative Wassermann in nineteen cases (seventy per cent.).

Reactions.—A few patients complained of gastric disturbances which seemed to pass away within twenty-four hours. In three cases there were severe local reactions, which almost went on to suppuration. The gluteal muscle around the site of injection was swollen twice its normal size, the inflammation extending up over the anterior superior spine of the ilium and down under the gluteal fold. The effect of this form of bismuth on secondary eruptions was that they did not clear up rapidly and in several cases persisted for four or five weeks.

In regard to the effect of bismuth on local lesions, it was noticed that in the primary initial sore, the first two or three injections had very little effect on the size of the chancre. We therefore doubled our dose and each patient thereafter received four c. c. of the oleate of bismuth which was equivalent to thirty-two per cent. of bismuth. There was no noticeably disagreeable effect from the increased dose, but we did notice that the skin lesions, both primary and secondary, disappeared more rapidly. The effect of the injections given in the gluteal region was the same as when we used the two c. c. or single dose. At times there was a slight hyperemia around the area of the injection, and at times a small indurated mass could be felt which persisted for four or five days. We were never compelled to miss giving a treatment on account of local reaction.

Urine routine.—The heat test examination failed to reveal albuminuria.

SUMMARY

Summing up these observations it may be said that patients treated with bismuth did not respond as rapidly as those which were treated with the arsenicals. This result, however, was quite in line with our expectations, for there is nothing in the history of the use of bismuth in the treatment of syphilis which would lead one to expect that it can displace the arsenicals. Painful swellings were at times produced in the gluteal region but did not persist long enough to cause any interruption of treatments. The clinical results obtained in these twenty-seven with oleobi show that bismuth can be a useful adjunct in our attack on syphilis, especially where the patient is unable to withstand the administration of salvarsan or neosalvarsan. In order to avoid inflammation of the mucous membrane, careful mouth hygiene is recommended. It is best to suit the dose to individual conditions, in separate doses of 0.10 gm. of bismuth.

This first investigation of oleo-bi will be followed by further use of the preparation, it being our intention to investigate the value of the product in the treatment of cases in which the arsenicals are already being used with a view to ascertain its value in the treatment of neurosyphilis.

Historical Medicine

Modern Medical Problems in Plato

JONATHAN WRIGHT, M.D.
Pleasantville, N. Y.

In Plato's *Republic* the medical man may find much to engage his attention in the hygiene and training, the regimen and the diet of the citizens. Pythagoras, so far as we know anything of this semi-mythical person, had in reality adopted the vegetarian diet which suited Mediterranean men not alone who dwelt in Egypt and Asia, where Pythagoras is said to have lived for years, but those along its northern coasts. With it were mixed various mystic taboos and the rigidity of a religious conformity which, if observed, allowed little variation for the varying constitutions of men. Plato doubtless had gathered the most of his lore largely from the Mediterranean people as to regimen and diet rather than exclusively from Pythagoras, to whom, however, much of his teachings have rightly been traced. Like Pythagoras, however, and dietitians generally, he seemed to think that if all men lived according to the menu of his republic there would not be much need of physicians. In this we get an echo of Egyptian Medicine in the Papyrus Ebers and in that of *IV Maladies* of the Hippocratic Corpus, which ascribed the etiology of all disease to the food. Like all dietitians, ancient and modern, he ignored the variability of the human species in the matter of food. The articles of diet which he had on his list were barley and wheat and olives and cheese and onions and peas and beans, figs, nuts and berries, quite a vegetarian bill of fare, and it is well to note that beans were not taboo as they were with Pythagoras. Where Socrates was going to get his cheese without cattle is not very clear, but he says that if in a state we must have herdsmen and the people must eat meat, then there will be a much greater need of physicians.

HYGIEIA AND ÆSCULAPIUS

Draught cattle, for agriculture, he seems to think necessary, but he sets his face against meat eating or admits it only under protest. Land for pasturage would then be coveted. We would have to take it from our neighbors. Meat and imperialism, fighting and doctoring and dying of disease when young instead of when old—these seem to be the calamities Plato means to escape in his republic, largely by diet, and in the Mediterranean lands few of us would have anything to say in cutting down meat in the diet to a minimum. He has a good deal to say against excesses of all kinds, especially athletics, against Syracusan dinners and Athenian confectioners and the complexities of license and luxury. When these multiply in a city halls of justice and doctors' offices are always opened and disease multiplies in the state, the doctors and lawyers "begin to give themselves airs, finding how keen is the interest freemen of a city take in them." High society has much concern with them. If the builders of Utopias did not thus drift into preaching, they could hardly find a reason for planning castles in Spain, but incidentally in the *Republic* we get thereby a glimpse of hygienic and social problems closely akin to our own.

Plato is here not alone alive to the causes of disease, as they were understood in his day, but as a statesman, though of the most theoretical and unsuccessful sort, he anticipated the theory of American doctrine in believing that if a republic is to survive, the greatest amount of moral and mental training should be exercised on those to become the governing classes. Plato's republic was essentially an oligarchy. Modern government, especially our own, is a democracy, in form at least, indeed essentially. The mass of men Plato excludes from the government, uneducated, we infer, and pushes into this class the outcasts from above, the incompetents, those who did not come true to type in his breeding pen. We admit them all to government and insist on instilling into all what Plato reserved for the chosen few, but we do insist on it for practically the same reasons. Those who govern must be as wise, as healthy, as moral as possible, and education thus becomes the most important function of the state. All forms of government, one changing into another, but all in history have, some sooner, some later, led to disaster, defeat and disintegration. An educated oligarchy, bred to govern, is gliding into a democracy in England and history, but not this generation, will know the result. As for us we desperately cling to the belief that universal education, to the limit, is our salvation, if there is to be any. It is the only thing which has not been tried, but Plato would have thought it queer doctrine and we are finding it hard to enforce, and we are discovering just as some kinds of food are not good for

some kinds of men, so some kinds of education are not good for some kinds of youth. We can carry the simile no further, for unlike the food we find some youth can take no education at all, or so little and so badly that they become, in spite of us, if not destructive to the state, a drag upon it.

Further, as an oligarch, Plato is with us modern democrats in insisting that not only the men but the women of the republic must be treated to the best of training, if they are to raise the best of sons for the citizenry. In Plato's day, too, men sat in clubs drinking cocktails and telling scabrous stories and pointing out "woman's place in the home"—so we can sum up in quite familiar language the old and the new retort. Socrates is made to say it is not worth while making much talk about weaving and the attention given to baking cookies and stirring the soup, or in arranging certain things for the goose and others for the gander. Many women are better than many men at many things.

"It is all just as you say."

"My friend, there is no occupation of those carrying on the work of the city for a woman because she is a woman or for a man because he is a man, but the gifts of nature are equally diffused in both sexes."

They differ of course just as men do. One has a gift for medicine or for music, or not. They may well become a part of the guardian influences of the city and there being no difference in their aptitude for this except as to their physical strength, he decides they shall strip and, with virtue as their robe, they shall take part in all the conflicts for the welfare of the nation, even military. In the gymnasiums they shall take their exercises naked like the men, though the world may laugh and jibe. It is easy enough to assign tasks of lighter muscular work and endurance to them, but their training should be the same.

Of course women do not go naked yet, but for the last hundred years, since the early Victorians, women have in general taken off a good deal of their clothes elsewhere than in the ball room and the bed room. In fact as athletes today they have fairly well approached the figleaf stage, if one is to judge from the Sunday papers. But Plato in other respects, too, is fairly abreast, despite his eugenic vagaries, with modern theory and practise. His theories at least are. It is for us to take note that he specifically refers to medicine as one of the arts in which women may excel. When we ponder over these passages in the *Republic* we can not but think of its author as isolated from the public sentiment of his time. Waving aside the indications in Homer and in the evidences of the statuary of Ancient Greece that woman bore some part in the medical art of the period, the paucity of records of their intimate life has left us so in the dark that possibly we have too easily accepted the view that woman was the ancient Greek's slave, that outside of harlotry they spent their time exclusively in baking cookies and stirring soup. But we refuse to go so far as to think of Plato adding nothing to the wisdom of his day, though we persist in the belief that he was an exceptionally gifted man in an exceptional epoch. There is much to show he took the world as he found it and he left it uninfluenced immediately by his labors, but later generations of men have been made immeasurably richer because he lived. In this sense we insist he added much to what he found. His advanced woman's rights doctrine could hardly have been put in practise except by more primitive men of matrilineal descent.

The hetaerae, of a social standing in Athens little understood by us, but evidently quite different from the woman of shady reputation today, may have been a phenomenon of the same spirit of the emancipation of women pervading the Athens of Plato's day as our own and absorbed by him. In so far as Plato borrowed from his environment his sentiments in regard to women in the *Republic* may have had such an origin. It is true, however, that Plato and Hippocrates have done much to create for us the atmosphere of Athens, yet we find in Euripides and Herodotus the intrusion of the same common influences. In the best known and the first of the Aphorisms of Hippocrates, life is short and art long, opportunity is fleeting, experience fallacious and judgment difficult.

All this is to be found in Homer, Herodotus, Euripides, Plato. The argument ascribed to Protagoras in the dialogue of that name turns upon the impotence of the senses in the face of truth. It was part of the intellectual atmosphere of Athens and the Greek civilization. We are still philosophizing about it. It has always been in the atmosphere of man pondering ever that soon he must die. It lives for us in Hippocrates because it is an ever present thought of thinking men.

There is a corollary to this doctrine of Protagoras which has implications of interest to us. He goes on to say there are innumerable things, meats, drinks, medicines, partly helpful to man and partly the contrary, some helpful to horses and some only to dogs, some to animals and some to plants. For instance oil harmful to plants is beneficial to the skin and hair of man and harmful to his vegetative system when taken inwardly. Plato does not insert "vegetative," but I do to draw attention to the principle of analogy Empedocles taught the world in comparing the absorption of the nutriment by animals to the sustenance the roots of plants draw to themselves from the soil. Protagoras points out its variations in both kingdoms. The earth produced men when Cadmus sowed the dragon's teeth in the old myth. Earth is the mother of us all is an apothegm we are familiar with. Hippocrates in the *Airs, Waters and Places* showed us how it influences us toward variations.

With the senses varying and things ever varying in their relation one to another, no one ever stepping twice into the same river, no wonder Hippocrates got from his environment the thought of Protagoras and Heraclitus—the thought that experience is misleading and foresight difficult. The wonder is that we so often forget it—Plato in his Pythagorean lurch toward excluding meat from the diet of every one, the silly recrudescence of it in our day, the ridiculous abuse of statistics, in cramming the squirming mass of always differing living things into one category. What possible interest to us are the average amount of calories a man needs to keep him going, when the real amount the patient requires depends on a thousand factors which no scales can measure? Man is the measure of all things Protagoras insisted—individual man, he meant, not man in the mass.

Fifty Years in the Practice of Medicine*

E. E. MONTGOMERY, M.D., LL.D., F.A.C.S.
Philadelphia

(*Concluded from page* 41)

These two radiant forces blend to facilitate the diagnosis of obscure conditions and certain restoration of health to persons previously regarded beyond relief by human skill. The x rays make it possible for Jackson and his school of bronchoscopists to follow the foreign body to its resting place in the smaller bronchi. I pause to speak of the last patient upon whom he performed tracheotomy. He had done intubation using, for want of a better, a tube rather small for the age of the child. Two days later the dyspnea recurred and not finding the tube in the larynx, feared that it had slipped into the trachea, and not desiring to add another he did a tracheotomy. The patient was relieved but the tube was not discovered. Two days later it passed through the intestine, having been coughed out of the larynx and swallowed. Today the position of such a tube would be made known by the rays. Thirty years ago a good x ray picture of the hand could be secured by a thirty minute exposure, now a better one can be obtained in one hundredth of a second.

The progress of development in fifty years in every department of surgery and in obstetrics has been marvelous, but valuable and farreaching as they have been in promoting health and saving life, they pale into insignificance when compared with the progress that has been made in internal medicine. Suspicion had long existed, that the occurrence of the plague, cholera, malaria, yellow, typhoid and typhus fevers, scarlatina, measles and syphilis were due to some infective organisms. In 1881, Laveran described some bodies found in the blood of malarial subjects which he called oscillariæ malaria, which subsequent to the further investigations of Marchifava and Celli became known as the Plasmodium malariæ. Singularly enough, Dr. Joseph Jones, of Louisiana, had been investigating the blood of malarial victims since 1859, and from his knowledge of the microscopic appearance of blood was able, not only to say that some stains, found upon the clothing of a man accused of murder, were not from paint, as he claimed, but blood, and that of a sufferer from malaria. A similar report on some stains on the door of a safe and the knowledge that the victim of the murder suffered from malaria, led to the conviction and execution of the murderer. This trial took place in 1877, while Laveran's discovery was not made until 1881. He had not, like Laveran, described the blood changes he had observed.

Although the most capable pathologists devoted themselves with the greatest enthusiasm to the study of these bodies, it remained a problem how they reached the blood of the victim, this, too, in spite of the fact that the mosquitoes were singing and stinging in all the affected areas, delightedly endeavoring to disclose their part in the tragedy. One could not but think, that if the mosquito could have knowledge of the situation, she would be inclined to exclaim:

"What fools these mortals be."

To follow the researches into the causes of these diseases is as interesting as a romance, and demonstrates that the research worker must be possessed of imagination. It is said that when Ross in India was investigating the filaria in the blood, the specimens supplied by one of the natives employed to make collections was much richer in organisms than those supplied by any other, inquiry disclosed that he was employed during the day and made his collections at night. Ross concluded that the organism completing its cycle, at night approached the skin where some suction insect received and transported to the next victim. The mosquito occurred to him as the insect to be investigated and his researches disclosed a species of the mosquito, the culex, as the promotor and transmitter. Later, in 1894, Ross was obliged to leave India as Manson began his investigations as to the medium through which malaria was transmitted and suggested to Manson that he investigate the mosquito and another species, the anopheles was found guilty.

Yellow fever was found endemic among the natives when America was discovered. Some parts of the West Indies and the coasts of Central and South America continuously supplied its victims. In 1802, when the French sent an expedition to Haiti, twenty-two thousand out of a force of twenty-five thousand men died of yellow fever in six months and those remaining were too enfeebled to make an effective invasion. The disease became epidemic, at times, in the coast cities of the United States from Boston to New Orleans. The disease was supposed to be transmitted by fomites and much dread was experienced during the Civil War that Confederate sympathizers would transmit the disease in infected clothing conveyed through Canada.

When Walter Reed went to Havana to study how the organism of yellow fever completed its cycle, he was already imbued with the inclination to investigate the mosquito, from his knowledge of what had been ascertained by Ross and Manson in their study of filaria and malaria. The particular mosquito was indicated to him by Dr. Carlos Finley, who had studied yellow fever since 1881 and had come to regard the Stegomyia fasciata as the responsible agent. In screened buildings Reed had nonimmunes sleep, for two weeks, in bedding and clothing used by yellow fever patients without development of a single case, when he had some of them bitten by the stegomyia and within forty-eight to seventy-two hours yellow fever occurred in such victims. Dr. Lazear and Dr. Walter Reed lost their lives in establishing the truth of this theory. Their sacrifice with the subsequent employment of the knowledge by General Gorgas meant the obliteration of yellow fever; made possible the building of the Panama Canal and permitted the establishment of health resorts in places that previously were but pest stations.

Great tracts which were formerly almost uninhabitable, from the ravages of malaria, now afford comfortable homes for a large population, and permit the conduct of great enterprises which were previously thought impossible.

Great as were the benefits secured to the race through the methods employed to control tropical diseases, they were nothing in comparison with the security and sense of safety obtained by the researches into the causes and methods of diphtheria and typhoid fever. The treatment of these diseases occupied a good part of the attention of the general practitioner in the years between 1875 and 1900. I was soon impressed with the futility of the treatment of diphtheritic croup with calomel and tartar emetic, the recognized agents. I saw these patients struggling for breath until a good part of the lung structure would collapse. I continually urged early tracheotomy, but was only able to secure its consideration when it was evident that nothing else would avail. I did the operation ten times before I was awarded with a recovery. I was the first physician in Philadelphia to practise intubation, and in 1888 gave an analysis of twenty-five patients on whom I had practised the latter operation; twenty-two of these were seen in consultation, in many of whom no measure was longer of any avail. The patients in my own practice all recovered. One patient had to wear a tube twenty-one days before it could be discarded. Of the twenty-five patients, thirteen or fifty-two per cent. recovered.

The discovery of the Klebs-Loeffler bacillus as the organism causing diphtheria and the development of serum therapy has made diphtheria a disease, death, from which, is inexcusable, as injections of antitoxine given the first day of the disease are invariably effective.

The New York Board of Health met December 15, 1894, and agreed to provide its physicians with antitoxine for the treatment of diphtheria. It was the first city organization to institute such measures. E. H. Place says the lives saved by diphtheria antitoxine since 1895 may be numbered in millions, yet fifteen thousand die annually in this country from failure to receive antitoxine at all, or to get it sufficiently early.

The employment of the Schick test and the employment of the toxine antitoxine injections in the positive cases ensures immunity for those thus treated for a period of three and one half years.

Typhoid fever presents another notable example of medical progress. During the Centennial year, 1876, the deaths from typhoid fever in Philadelphia numbered 761, which with the population of the city at that time was more than a hundred in 100,000 while in 1923 the mortality from typhoid fever was but 1.55 in 100,000. The deaths given for 1876 were but part of the record, for sick and infected visitors returned from the exposition to nearly every hamlet in the eastern half of the United States, many of them to die, causing Philadelphia to lose more in reputation through this disease than she gained by the Centennial Exposition. Purer water, cleaner streets, and better drainage have done much to lessen the mortality. Director Krusen informs me that the records of mortality from this disease in Philadelphia in 1923 is better than that of any large city in this country. The possibility of the control of typhoid fever is better shown by consulting the army records, which present the results of preventive measures that were made obligatory.

Chantemesse in 1896 announced that he had procured a serum from an inoculated horse, the inoculation of a guineapig with one fifth of a drop of which protected it against a dose of toxine, fatal to an unprotected animal. Further investigation so demonstrated its efficiency that in the late World War its use was made obligatory. During the Spanish-American War the sickness and casualties from typhoid fever became a national disgrace, as one soldier in every seven had the fever and one in seventy-one died.

Among the four million serving in the late war, there were but 1,305 cases of the fever, and but 156 deaths. This was equivalent to one case occurring in every 3,756, and a death in every 25,641. Had the incidence and mortality been in proportion to that of the Spanish-American War, there would have been 571,428 cases of fever and 56,388 deaths.

Probably no disease has received more consideration during the last fifty years than has tuberculosis. With the discovery of the tubercle bacillus by Koch and the introduction of his antituberculous serum it was hoped that the disease might be exterminated. Unfortunately, no serum has effected the expected results, and this disease continues to levy a heavier toll than is exacted by any other. Much has been accomplished by sanitation, in better housing and living conditions, and the recognition of the important part played by the administration of good and by living in the open.

Ransome says that in Great Britain phthisis has steadily declined from 3,800 in 100,000 in 1838 to 1,305 in 100,000 in 1896. In Philadelphia in 1873, with a population of less than 600,000, there were 2,291 deaths from pulmonary tuberculosis. In 1923, with a population of more than 1,800,000, there were 3,674 cases reported, with 2,162 deaths. With, at least, three times the population, one hundred fewer deaths occurred.

Investigations in later years have changed our views on many obscure conditions. What are called focal infections, originating in abscessed teeth, diseased tonsils, suppurating sinuses, infections of the gallbladder, appendix, seminal vesicles, prostate or cervix, have been found to have been the source from which originated arthritis, bone affections, chronic inflammation of the ovary and other lesions. It is quite possible that many persons are unnecessarily mumbling their food, sans teeth, or have sacrificed inoffensive tonsils, but the knowledge that such infections may cause disease through the blood, has afforded means to secure improved health, lessen discomfort and prolong life.

One naturally shrinks from the thought of advancing age, with its limitations; its assurance of lessening tenure of life; the possibility of lowered physical and mental vitality; but it has its compensations. It can not but be a source of gratification that one has known men who have done much to make medicine creditable; men like Atlee, Pancoast, Gross, Agnew, Marion Sims, Emmet and Battey; to have worked with Goodell, Pepper, Tyson, J. M. DaCosta and Osler; to have been associated in medi-

cal conventions with men who have elevated and dignified our profession. Among these the name of General W. C. Gorgas projects as a beacon light. Under his ministrations yellow fever was obliterated from the list of death causes in Cuba, where it had been continually endemic for 150 years. Yellow fever and malaria were banished from the Isthmus of Panama, rendering deaths from all causes there, but eight in 1,000, while at the same time our northern cities had a death rate of fifteen in 1,000. His work did more to make possible the Panama Canal than the work of its engineers. The morbidity and mortality rates would be creditable in the best health resorts.

Was it not fortunate that such a man could direct the medical service in the World War? The record already given of the typhoid fever incidence in the army has demonstrated his efficiency. In Great Britain he would have been knighted and placed beyond want for the remainder of his days. When the inevitable time came for his retirement from the active service of the army, he was not permitted to rest, but was called on to clean up the pest places of the world. South America, Egypt and India, all demanded his service. What wonderful privileges are enjoyed by the practitioner of the present day? His is the heritage of the last fifty years of progress, not exceeded by any previous century in the world's history. Tests and reactions are at his command to dispel all doubt. The skeleton, the various organs and their actions can be rendered visible at his command.

Pathology, physiology and chemistry, instead of being abstract sciences remote from application, are his handmaidens, to make easy his diagnosis, and ensure his success in treatment. With all the opportunities he has gained, it becomes a question whether he has not lost quite as much. The increased time he has had to devote to the preparation, for the practice of his profession, in the years when a man is forming the habits and impulses, which are to actuate and direct his life; the inability of any one mind to retain all the details necessary for scientific diagnosis and practice, and the intense interest of the scientific side of the investigation, have necessarily led to specialization.

The dependence upon tests and reactions, the greater accuracy of such scientific investigations have served to exclude the practitioner from the study of the individual, to cause him to lose that psychic inspiration so essential to the encouragement of the depressed physically and mentally ill. One has to guard himself against regarding the patient as the means toward a scientific goal, and lead him to forget that the interests of the individual should ever have first consideration.

How often is seen a man well qualified for practice, possessed of the requirements for diagnosis and treatment, failing of success, while another, much his inferior in intelligence and scientific attainments, acquires a large practice, because he possesses that human touch; that ability to make his patients feel that their interests only, are his first consideration and thus is acceptable to all who come under his influence.

The physician today should be unsparing in his acquisition of scientific knowledge, unfailing in his efforts to exercise the most approved tests and reactions, faithfully seek to employ the best treatment, but must never forget that the acquisition of the confidence of his patient is the best drug he can employ. Its acquisition is the goal, for which he must constantly strive, in order to attain to the highest success.

When the author considers what has been achieved, what is being done and what seems to be gilding the coming dawn, he is constrained to exclaim:

> "Oh! to be alive in such an age,
> When every year's a wonder stage."

The Breviarie of Health, by Andrew Boorde. —Dr. W. G. Aitchison Robertson writes (*Annals of Medical History,* December, 1924) that it is not difficult to discover in reading this early medical work that we have in it an example of the priest physician in the early days of medical practice.

Andrew Boorde or Börde was born at Boords Hill in Sussex, England, about 1490, and thirty years later was made suffragan bishop of Chichester. He was a Carthusian monk and for many years lived an austere life, fasting and abstaining from all forms of animal food. Finally in 1528 he wrote to the prior "I am nott able to byd the rugorositie off your relygyon," which brought him a dispensation to trâvel abroad "for to have the notycon and practes of Physyche in divers regyons and countres." He returned to England in 1530. Having attended the Duke of Norfolk in a dangerous illness and having secured his favor, he was "convocated to wayte on his prepotent mageste," Henry VIII. But not considering his medical education complete, he visited the universities and schools of Orléans, Poictiers, Toulouse and Montpellier; also Wittenberg, Rome and Compostella. When he returned he was disciplined by the church and kept a prisoner until released by his friend Cromwell, who sent him abroad on a political mission. Upon his return he spent some time in Glasgow and later in London, but was not looked upon with favor in either place.

Dr. Robertson quotes somewhat at length from the book, *A Propheme to Chirurgions,* which contains some excellent points for consumption today curiously mingled with most childish superstitions: "Masters of Chirurgerie ought to bee esperte in their facultie, having good wittes and memorie, evermore to be diligent and attendable about their cures and able to minister such salves and medicines as is according to the infirmity. They ought also to be wise, gentill, sober, circumspect and learned and not dronken and to promise no more than they are able to perfourme with God's helpe and not to be boisterous about his pacients but lovingly to comfort them. . . . Chirurgions much know the operation and the conjunction of the moone and in what signe the moone is in every day and to know what signes be attractive, what signes be recentive, or expulsive or digestive. They must also know the operacion of all manner of breades, of drinckes and of meates, and to have ever in a redines their instruments and their salves. In perillous cases one Chirurgion ought to consult with another and to have counsell of a Docteur of Phisick, for ther is no man can be sure to help a man, as God knoweth, who keepe us all. Amen."

Practical Therapeutics

MERCURY, NOVARSENOBILLON, QUININE AND LEUCOCYTOSIS

Burr Ferguson, M.D.
Southampton, England
U. S. Public Health Service

Something over a year ago it was proved in the Municipal Laboratory of Southampton, with the aid of the former Borough Pathologist, Dr. Harry Simson, that the intramuscular injection of salicylate of mercury is followed by a marked increase in the production of white blood cells, so explaining to my satisfaction the potent influence of this drug on most of the manifestations of syphilis, furunculosis and infected wounds. In the treatment of the latter infections I have seen uniformly good results for about eight years in various parts of the world. Always up to this time the drug was used in the belief that the mercury was having its socalled specific influence on the treponemæ and that I had been fortunate in finding that this effect was so easily extended to the pyogenic organisms.

To me the knowledge that the oldest drug we know induced an increase of white cells seemed very much more logical and reasonable in explaining its satisfactory action, in the treatment of the disease for which it is principally used, as well as the others, in which I had seen its powers manifested. This chain of reasoning seemed clear. It is a matter of common knowledge that a man in the best condition, at "the top of his form" has a high white cell count. One in such condition can stand exposure to most infections unharmed. In one not so fit, when harmful infecting organisms do find lodgement, there is, in most infections, an immediate rise in the white cell count. So one would conclude that these cells were directly involved in the phenomenon of resistance.

Next we find that the oldest and most widely used drug known to medical men produces a very marked increase in these apparently protective organisms. Did it not seem cogent that there is a distinct promise in the treatment of other infections in the application of the principle of an easily induced increase in white cells?

I thought that it did, and the year's experience here in the application of the idea has been far more successful than I had ever hoped. At my suggestion encephalitis lethargica in the Liverpool City Isolation Hospital, Fazakerley, is said to have been successfully treated in application of this principle, by Dr. C. Rundle, officer in charge and his staff, thirty-nine patients being given an average of four injections each of one grain of the salicylate of mercury in oily suspension. All recovered satisfactorily. In some the improvement is said by Dr. Rundle to have been striking. One patient who came in on the ninth day of the infection died after having had one injection.

Thirty-one cases of trachoma among Poles and Russians who were detained because of this infection at Atlantic Park, Eastleigh, Hampshire, have been treated by Dr. Frank McGee, the medical officer in charge, and by Dr. Arthur Zorab, of the Eye Hospital, Southampton, as consultant.

Treatment of these patients on the principle of the induced increase of leucocytes was begun in November, 1923. In March they began to be passed as cured of trachoma by all examining officers here and in New York and in Montreal. So far twenty-five of the original thirty-one patients have been declared cured and are now residents of the United States and Canada. In these cases from twelve to thirty-five injections of salicylate of mercury were given. In four of the remaining cases novarsenobillon is being given with good results, as will be told by Dr. Seager Thomas.

The usual local treatment of rolling the lids and the application of copper sulphate, one per cent. solution of perchloride of mercury, has been used, together with the injection of salicylate of mercury given once a week during periods of six to eight weeks, a rest being given to allow the individual to reestablish a sensitiveness to the mercury. This is done because we have learned that with each successive dose or injection the rise in the white cell count is diminished, finally becoming negligible after six or seven weeks; no increase in white cells—no noticeable change in the trachomatous lesion. This seems to me to be the only logical reason, for the instructions given in college, borne out by the experiences of the following years, that in the treatment of syphilis, mercury must be given in series or courses. Experience taught that after a few weeks of mercury obstinate lesions failed to continue to improve. A rest being given, the administration of mercury was followed again by improvement of the evidence of the infection.

Blood counts showing rapid decline in the powers of the stimulation of the production of white cells after repeated injections of the drug, would seem to furnish a reasonable explanation.

In the attempt to extend the principle of the treatment of infections by this induced increase in white cells I have seen or known of rapid, certain and satisfactory results in arthritis, asthma, bronchiectasis, pyelitis, acute otitis media, eczema, not yet diagnosed abnormalities or infections of the skin, iritis, iridocyclitis, carbuncle and hay fever, after one to three injections each.

Last spring at the usual time, a friend had his fourteenth recurrence of hay fever, conjunctivitis, congested nasal membranes with cough, sneezing and ordinary discomfort of the infection. On the theory that more white cells would help him, they were induced to mobilize by the injection of salicylate of mercury. On this day he had used seven handkerchiefs. I saw him twenty-four hours after the injection. There was no evidence of any irritation about the eyes, no swelling of the nasal membranes, his breathing was clear, and he proudly showed, still folded and not used, the four handkerchiefs with which he had provided himself on leaving his home in the morning. I had hoped for improvement but never had I thought it possible for one to be so changed in twenty-four hours. I at once called up

Dr. Arthur Zorab, whom I knew was regularly using the salicylate to tell him of the unusual happy result.

Dr. Zorab on hearing the words hay fever and salicylate said: "Go no further, I know, I have just used it on two cases with equally good result." So Dr. Zorab has priority in the use of the drug for hay fever, and he used it on twice as many cases as I did. He used it to better effect, for there was no return of the infection in his cases. The evidence of infection returned in my friend in six days, not as severe as at first but enough for much discomfort. The second injection of the salicylate was not so potent as the first. His discomfort continuing on the third day of the recurrence, in the belief that novarsenobillon also stimulated the production of white cells, he was given .45. He grew rapidly better and had the best year he has had for fourteen years.

Not having ready access to any laboratory, the belief that novarsenobillon and quinine derived their potency from their power to stimulate the production of white cells, was unproved for six months. Then the belief became so strong that a call was made on Dr. Seager Thomas, a pathologist in Southampton, at his laboratory. Dr. Seager Thomas was cordial and showed every evidence of a kindly will to aid in the proof or disproof of the idea. He will tell of his findings in the following paper, and of his observations of the use of novarsenobillon in furunculosis and trachoma, of the longer duration of the induced increase in white cells, of the apparently longer continued sensitiveness to the drug, of the effect of the other specific quinine on the white cells.

With the observation of the effect of an increase in white cells on infection for so long a time, and the additional proof of the action of novarsenobillon and quinine, the promise held out for satisfactory use by an extension of the application of the principle, seems great. For surgeons to add to the directions for the preparation of a patient for operation, the administration of three tenths to six tenths novarsenobillon on the morning of the day of operative procedure would be to muster a potent prophylact against infection. If I am not altogether wrong, the operator will see wounds close faster, with seldom a stitch abscess, than he has ever seen before. About the usual time for the appearance of infection, forty-eight hours after the operation, the white cell count will be about the maximum, and according to all my experience the pyogenic organisms will have a short life. In obstetrical cases the administration of the drug after delivery of the infant, in order that this greatest increase be had two days after, will hasten the repair of the cervix and other wounds and add to the comfort of the convalescence. In fresh lacerated wounds, where the probabilities of infection are great, novarsenobillon in proper amount will be useful. From the effect I have seen of this increase in white cells in the treatment of pleurisy and bronchiectasis the latter case being one of Dr. W. A. Elliott's, of Southampton, I feel sure that good results will be had in the treatment of either bronchopneumonia or lobar pneumonia from the use of novarsenobillon.

For those who still have a doubt, let me suggest that they take a healthy control, not a regular drinker, for the blood of every regular drinker I have seen counted is abnormal. Usually counts of from 12,000 per c.m. to 20,000 per c.m. increase to 18,000 to 23,000 per c.m. by mercury or novarsenobillon. So the regular drinker is not a good control. But take a healthy control, make a blood count, give him novarsenobillon, other counts in twenty-four and forty-eight hours and some interesting blood changes and fields will be seen.

THE ARTIFICIAL INDUCTION OF LEUCOCYTOSIS

G. R. Seager Thomas, M.B., B.A. Cantab, M.R.C.S., L.R.C.P. Lond.

Southampton

There has recently been a fairly considerable use of salicylate of mercury in a more or less empirical manner for the treatment of a variety of conditions, notably trachoma, staphylococcal infections, e. g., furunculosis, and encephalitis lethargica.

The major portion of this therapy has been somewhat spasmodic and disconnected, but for many years in several quarters of the globe salicylate of mercury has been used consistently in many different types of cases by Dr. Burr Ferguson of the United States Public Health Service. Dr. Ferguson's communication refers to his experiences in this direction and to that article these notes are simply a pathological postscript.

His successes with mercury, to which he refers as one of the specifics, led Dr. Ferguson to attempt the substitution of novarsenobillon or alternatively quinine for the mercury. His results need not be described again here. Finding that similarly satisfactory effects followed the use of these drugs also, he felt that a hypothesis to explain provisionally the rationale of the treatment would be of interest and value. His observations led him to the belief that these drugs owed their efficacy to a power of artificially inducing leucocytosis.

This view led to a certain amount of amicable controversy, and I, on being offered the opportunity of investigating the leucocyte variations in a number of subjects, considered that it would be only sensible to test Dr. Ferguson's hypothesis by a rigid application of the scientific method.

The first stage—recording of observations—is supplied by Dr. Ferguson's own records of cases and those of other medical men.

The second stage—formulation of a provisional hypothesis—is supplied by Dr. Ferguson's suggestion that the drugs act as inducers of leucocytosis.

It next becomes necessary to perform a number of carefully controlled experiments, record the results, and see whether these are in accordance with the provisional hypothesis. The work is in active progress now, and an indication of the results obtained is the purpose of this communication.

Should the results obtained support the provisional hypothesis, or a modification of it, then we can be said to have a theory of the action of these drugs, and such a theory should be capable of application, 1, satisfactorily to explain apparent exceptions, and 2, accurately to predict the influence of one of these drugs upon the blood picture in a given case. Such

applications of the theory if successful, constitute scientific proof of its correctness. Both these exercises have been performed.

The reason for publishing any of the laboratory findings at this admittedly early stage of the investigation, may not at once be clear. It has been reported that several laboratories in Germany are busily engaged in the search for an agent for the artificial induction of leucocytosis. It seemed therefore not unwise to record the fact that an investigation into just such properties possessed by well known drugs had already been initiated. It is not claimed that the necessary experiments, observations and correlation of the results are as yet in anything but the very earliest stage.

I have seen a number of successful cases, most of which were treated by novarsenobillon (there was no reason to suggest syphilis, nor was the drug administered for this disease). A series of cases of trachoma were among those which made the most vivid impression. There is, however, no intention to refer to the purely therapeutic aspects of these cases here, as favorable testimony from this point of view is forthcoming from clinicians.

An indication of the hematological results is given below:

SALICYLATE OF MERCURY

WHITE BLOOD CELLS PER C.MM.

Subject	*Before intramuscular administration of one gr. mercury salicylate*	*24 hours later*
D. M.	7,000	20,400
M. P.	8,000	17,000
M. C.	18,800	21,800

BIHYDROCHLORIDE OF QUININE

Subject	*Before intramuscular administration of seven and one-half gr. of quinine bihydrochloride*	*24 hours later*
J. M.	11,000	14,000
C. P.	9,300	12,700

(five gr. only given)

NOVARSENOBILLON

EFFECT OF INTRAVENOUS NOVARSENOBILLON (DOSE VARIES FROM .3 TO .6 GRAM, ACCORDING TO SIZE OF SUBJECT)

Subject	*Before N.A.B.*	*24 hours later*	*7 days later*		*24 hours later*	*7 days later*
B. F.	7.200	10.200	9.800	Second injection given on seventh day	.....	.....
J. M.	10.400	22.800	21.800		.....	.....
C. P.	7.200	10.200	9.300		.....	.....
K.	7.600	10.600	12.400		17.100	14.600
B.	8.800	13.000	13.800		14.400	.....
R.	7.900	12.500	10.800		13.200	.....
G.	7.400	12.600	14.000		10.600	.....
M. G.	10.000	14.000	12.000		.....	.....

It will be seen from the foregoing tabulated results that mercury, quinine bihydrochloride and novarsenobillon are powerful inducers of leucocytosis. The investigation with regard to quinine was not continued for the following reasons: 1, the injection is distinctly painful, and 2, it appeared to have no advantage over mercury or novarsenobillon.

Previous leucocyte counts carried out for Dr. Ferguson (at other laboratories) have shown that a tolerance to mercury is somewhat rapidly established. The leucocyte count returning early to normal and being comparatively little raised by repeat injections.

In novarsenobillon we have an agent practically painless in administration and at least as safe as either of the others in suitably selected cases. Its first effect upon the leucocyte count is at least as marked, its period of maintained leucocyte increase much longer, and its effect at repeated injections much greater and more constant than in the case of the mercury and the quinine. There seems to be very little doubt, that in novarsenobillon and its variants we have a very constant and dependable agent for inducing leucocytosis, where this is desirable.

One of the apparent exceptions was a case in which the count before injection of novarsenobillon was 17,000 per c.mm. and twenty-four hours later had dropped to 12,600 c.mm. The result, however, had been anticipated as one of two probable results of the injection. The subject was a patient who had a large, acute boil. It was anticipated that either 1, the boil would discharge completely, within a few hours of the treatment thereby rapidly removing the cause of his natural leucocytosis, and producing a drop in the count, which, however, would be artificially prevented from returning to normal, or 2, he would have added to his natural, a further artificial leucocytosis if the boil still persisted as a focus of pus under pressure, and yield a count somewhere near 25,000.

I have suggested in order to explain sundry cases where the customary relief does not occur, a modification of the simple leucocytosis theory of Dr. Ferguson. It seems but reasonable to believe that however successful one may be in inducing leucocytosis, the army of phagocytes will be ineffective if unattended by munitions of war, the multifarious antibodies, and it is now proposed to observe the effect of the administration of novarsenobillon to patients whose specific antibody formation has been stimulated by autogenous vaccines. It appears to me a more sound rationale to bend to one's purpose not the cellular factors alone, but also the humoral factors of immunity.

At first differential white cell counts were made but it was soon seen that with slight exceptions (in one or two cases there was slight eosinophilia; in others increase of endothelial cells and occasionally some polymorphonuclear increase) the variations in the relative counts remained within the limits of the normal. The differential counts were then discontinued.

These investigations will take time, but in due course the complete record will be to hand. It appears to be a promising field in which laboratories having at their command a greater abundance of material than is at our disposal here, could find a very valuable sphere of activity.

INDUCED LEUCOCYTOSIS IN THE TREATMENT OF INFECTIONS

W. A. Elliott, M.B., B.S.

Southampton

Some months ago Dr. Burr Ferguson of the United States Public Health Service, Southampton, spoke to me about the results which he had obtained by the use of injections of salicylate of mercury for treating infective conditions. His great faith in and enthusiasm about this method of treatment impressed me so much that I decided to try it on some suitable cases in my practice. The method consists in the intramuscular injection of a mixture of salicylate

of mercury in goose oil, one c. c. being injected at intervals of one week up to four or six doses, or less if the desired result is obtained earlier. This is the usual method of course in treating syphilis.

Some of the cases which I tried were as follows:

Case I.—Patient aged forty-six years with a condition of chronic infection of the lungs, following pneumonia, bronchiectasis. This showed itself in attacks of pyrexia and chest pains whenever this patient had a chill, which confined him to bed and made him extremely ill for a time. There were physical signs of chronic pleurisy. This man had been immersed in the sea for many hours after a torpedo attack on his ship during the war, and it was subsequent to this that his chest trouble commenced. During one bad attack I waited until the more acute symptoms had subsided and then gave him two injections of salicylate of mercury at an interval of five days. The result was a complete recovery with abatement of all chest pains, and free and easy breathing resulted. Moreover, the most encouraging result of the treatment was the enthusiasm of the patient himself, who stated that he felt a "different man." Previous to these injections he stated that he had a chronic depression of spirits, with a feeling as though there was a load on his chest and weights on his legs. After the injections he was buoyant again, and walked more lightly and with the elasticity which he used to have before his attack of pneumonia. The good results obtained have so far persisted.

Case II.—A patient aged fifty-one years was suffering from a fairly large carbuncle on the back of the neck, with which he was confined to bed and suffering from much pain. The carbuncle was having the usual treatment of boracic fomentations and was steadily enlarging and forming a central crater containing a large mass of hard, dead epithelial débris. I gave him an intramuscular injection of one c. c. of salicylate of mercury, and on the following morning there was a most perceptible softening of the mass. It continued daily to get rapidly better, the slough being cast off and an uneventful recovery ensued.

Case III.—A female patient, aged between fifty and sixty years, was suffering from a chronic dermatitis of the whole body with bleb formation and much irritation. I treated this with calamine lotion, and in several weeks there was a marked improvement over the whole body, but new formations of blebs continued to appear. I therefore gave her two injections of salicylate of mercury at an interval of five days, and complete recovery ensued, no further outbreak of blebs occurring. The condition had been troubling her for many months.

I may here state that for local infections of the skin I have long had a strong faith in calamine lotion just as Dr. Ferguson has in the intramuscular injections of salicylate of mercury. It seems to have a peculiar, or what is usually termed a specific effect in healing skin infection. This is evidently something apart from the mere killing of germs by an antiseptic action of the agent used. Dr. Ferguson has investigated the results on the blood of the injection of salicylate of mercury with the assistance of Dr. Simson, who was tuberculosis officer at Southampton at the time. His results are most illuminating, as they show that an immediate general leucocytosis occurs in the blood within twenty-four hours of the injection. Moreover, he has found that certain salts of arsenic produce a similar effect. Also that quinine, the socalled specific for malaria, produces a similar leucocytosis, though not so pronounced in extent. The conclusions drawn are, that the specific action of mercury, arsenic and quinine in certain diseases are all due to a general leucocytosis produced in the blood.

In my opinion the local use of calamine lotion produces a local area of leucocytosis which causes its socalled specific action in skin infections and the same effect is produced by mercuric ointment. In this case the salt of the heavy metal zinc produces the result locally. I have repeatedly noticed a bluish coloration of the skin around the areas treated with calamine lotion, suggesting a blood change at that area. This leucocytosis of the blood is considered by Dr. Ferguson to be the reason for the happy results which he has repeatedly gained by the intramuscular injections of salicylate of mercury for infective conditions, the increased number of leucocytes killing the infective agents.

The treatment of the septic sores and chronic boils occurring during the hot seasons among troops, in tropical climates, such as India and Mesopotamia, could, in my opinion, be most successfully treated by this method of intramuscular injection of certain salts of mercury or arsenic, instead of the cumbrous and costly production of vaccine for injection.

Metabolic Changes Associated With X Ray and Radium Treatment.—E. C. Dodds and J. H. Douglas Webster (*Lancet*, March 15, 1924) conclude as follows: 1. Exactly similar results were found in patients treated with x rays or with gamma rays. 2. The changes in metabolism produced in the patients were found to vary with the site radiated, as irradiation of the head, thorax, and limbs produced no change in the metabolism of the cases examined, but radiation of the abdomen and spleen produced definite urinary and blood changes—namely a sudden fall in the twenty-four hourly amounts of urea, uric acid, ammonia, titratable acidity, creatinin, total nitrogen and phosphates; the volume of the urine was also greatly decreased. After about three days the excretion of these substances again became normal. The chloride content and diastase showed an immediate increase, returning to normal in three to six days. The blood showed mainly a marked decrease in the urea. The feces showed an immediate increase in the fecal fat content. These results show that the effects of abdominal irradiation are due to a temporary inhibition of the function of the principal abdominal glands, such as the liver, pancreas and kidneys. Irradiation of the cervical region produced no change in the metabolism as evinced by study of the blood and urine except an immediate fall in the excretion of urinary creatinin. 3. Cases of very well marked x ray sickness showed no change and the cause was apparently psychical. 4. Cases treated prophylactically with calcium chloride, etc., before irradiation and with sodium bicarbonate showed less reaction.

Editorial Articles

PRACTITIONERS AND PUBLIC HEALTH

A short time ago a sanitarian remarked to a conference of rural health workers that "At the present time the practising physician is the great obstacle to public health advancement." This severe arraignment was tempered by the statement that public health owed its conception, birth and life to the medical profession and that the obstacles which were now being placed on the road to rural health improvement were the symptoms of a misconception by the medical profession of the intent and purpose of public health endeavor. The speaker also expressed the opinion that this arose out of an apprehension that public health work might eventuate in state medicine, a nebulous hypothesis which presupposed that public health workers were endeavoring to transfer the treatment of the people from the hands of the private practitioner to those of a public medical service.

It is not the leaders of medicine and surgery who entertain such ideas. They realize fully that should state medicine ever come into being, the initial movement will come from the medical profession itself. For the most part, it is the underpaid and overworked country practitioner who sees, in the rural public health movement, a menace to his already too scant income. Country doctors, who used to rely on autumnal typhoid fever to provide food and fuel for the winter, have seen this source of income done away with by antityphoid fever campaigns, while the measures for the control and prevention of diphtheria, scarlet fever and many other communicable infections have deprived them of a considerable number of fees. He has seen in adenoid and tonsil clinics an invasion of his field of practice and naturally he has concluded that the welfare work which was being done under the guise of public health, constituted a further menace to his economic welfare.

In certain sections there is an element of justification in this. Overzealous public health workers have, unfortunately, invaded the field of curative medicines but in the final analysis this has done the practitioner good rather than harm. The dental profession has been quick to realize that the examination of the teeth of school children means an increase in their practice and they have seen in public health propaganda a genuine advancement of the cause of dentistry. The practitioner of medicine has been slower in realizing that out of public health work comes a greater realization of the necessity of maintaining the human organism in healthy functionation at all times and that this means that he will be called upon to assist people in keeping well rather than to try and patch them up after serious physical damage has been done. It is time that the practitioners of medicine and of public health should get together on the basis of mutual understanding, and it is believed that this will result advantageously to both.

As a corollary to the promotion of better understanding and cooperation between the workers in preventive and curative medicine, it is suggested that greater attention should be paid to the matter in the curricula of medical colleges. If the student of medicine can be made to understand early in his career that public health, far from being an agency which menaces the economic welfare of the physician and surgeon, is a genuine aid to him not only because of the improvement which it will bring in his practice but also because a healthy community is far better able to pay its bills than one which is unhealthy, great and lasting good will be accomplished.

THE SPEECH OF MODERN LIFE

Conditions of living in civilized countries have changed so considerably that the medical man of the present day is confronted with problems of which the practitioner of a few years ago knew little or nothing. Epidemic disease has been combated successfully and domestic and personal hygiene is now receiving or about to receive the attention to which by its importance it is entitled and we are probably entering upon an era in which preventive medicine will play the chief part. However, there are diseases prevalent, some say rampant, which are largely due to, or at least greatly aggravated by, the speed at which life is lived. This is a phase of preventive medicine which cannot be overlooked.

At the conference of the Interstate Postgraduate Assembly of America held in the first week of June in London Lord Dawson of Penn, a well known British physician, gave a noteworthy address. The leaders of the medical profession everywhere recognize that medical and surgical treatment is tending towards prevention rather than curative treatment.

The late Sir James Mackenzie was one of the first thoroughly to appreciate this fact and now all the alert members of the profession are following in his footsteps. Lord Dawson pointed out that the places which used to be held by the specific fevers in the sphere of bodily ailments were now being taken by subinfections which deteriorated people slowly rather than killing them quickly. In other words, it is the chronic diseases in place of the

acute affections which we are called upon to fight and many of the causes of these subinfections lay within us. There was a contrast between the way in which the microbes of the acute infections invaded us in force, laid us low and on our recovery left us alone, and the fact that the microbes of the subinfections might be like the poor, always with us. They might share our active lives, troubling us but little when we were fit, and damaging us when we were unfit.

For these subinfections measures of public hygiene were of little avail. It was the condition of the host that mattered. As for the condition of the host, a measure of struggle would make for health, but the difficulty of modern life lay in the overdose of struggle. Modern life was likely to produce, not strength but stress, and particularly in the efficient types of citizens. The central reason for this was that material progress in all that concerned movement had been so rapid that it had outstripped man's rate of adaptation. Instead of taking a rest from the tension of business, the active man of affairs of today made of what should be relaxation as strenuous a time as when he was participating in his daily work.

The pursuit of pleasure with many had become as arduous and tiring as the travail of commerce or whatever he might be engaged in. It was a rush and hustle always and of course this tendency had been immensely aggravated by the rapid means of locomotion. Nor were the effects of high speed life confined to those who actively took part in them as people were both at the same time impressionable and endowed with slight staying powers and the mere fact of living in such an environment brought men to grief.

Attention was directed to the point that much might be done by a more careful selection of the careers and employment of the people. When society reached a wider vista doctors would direct the health of the community rather than spend so much time in undoing bad effects. But the speaker was not in favor of periodic examination which would produce anxiety and do more harm than good. Such work could only be done by one's private physician, and not by sending people to stand in a queue for examination. With regard to remedies for this parlous state of affairs, if they as a profession cast their minds ahead, they would more and more become an educational body, and get away from the bottle medicine and what it stood for. They would teach the hypersensitive man to maintain relaxation.

Psychological culture had a usefulness parallel to physical culture. Rest of body and spirit, and of spirit more than body, is what is required to relieve the strain of an overstressed civilization, and although Lord Dawson did not say it, the hypersensitive man and woman of the period must be taught to rest.

For long this journal has preached the gospel of prevention and it is encouraging to know that the shining lights of the profession and moreover the public are beginning to recognize the truth of this teaching. In this country more than in any other King Hustle holds sway and therefore it is highly appropriate that an American medical journal should have been one of the first and quite the most insistent and consistent to spread the doctrine of preventive medicine in all its aspects. It is a fallacy to believe that the development of preventive measures will injure the practitioner of medicine. It will alter, to some extent, the mode of practice but progress in any *phase of endeavor* brings change. Man is an adaptable animal, the war has driven home that fact, and the medical profession will soon fall in with views inspired and dominated by sound common sense.

PHYSIOTHERAPY

The organization of the American Academy of Physiotherapy was brought about by a need in this field of medicine. The aims of the organization are the standardization of the subject on a scientific basis, the prevention of overenthusiasm concerning methods which have not been thoroughly proved, and the bringing of physiotherapy into its proper place in the various departments of medicine.

The academy is composed largely of medical men who were recognized for their ability in physiotherapy during the world war. It is most fitting, therefore, that the head of physiotherapy in the Army Medical Corps should be chosen as president of the organization, Colonel Frank B. Granger, of Boston. The following excerpt is taken from his address before the first convention of the American Academy of Physiotherapy:

The academy has been organized along broad lines. Provisions have been made for sections such as hydrotherapy, massage, muscle training, physical education, electrotherapy and mechanotherapy. In addition, general sessions will coordinate all these various branches into an intelligent and coordinate whole as an adjunct to all other medical and surgical measures in the treatment of pathological conditions. When this shall have been accomplished the challenge of the cults will have been answered.

In order to accomplish this the support of physicians of the highest professional standing must be enlisted. Therefore it has been proposed to have as associate members those who, while not actually practising physiotherapy, recognize its value and prescribe it for selected cases. This list should and will include the leading men in medicine and surgery.

For active members the test should be professional standing, scientific knowledge of physiotherapy as

well as of medicine in general, personality and adequate clinical experience. The standard of admission should be so high that the acceptance of a candidate would at once stamp the applicant as a sound, safe and scientific physician.

The high standard of work done by the members of the organization was revealed in the papers read at Atlantic City during the convention in May. Among the subjects discussed were: Treatment of tuberculous joints and other bone lesions, physiotherapy in reconstructive surgery, the various aspects of ultraviolet rays including physics and the effects on blood chemistry, tuberculous and other conditions, various aspects of electrosurgery and hydrotherapy, while physics in medicine and diagnosis from various angles were carefully discussed.

The next annual meeting of the academy will be held in the Copley Plaza Hotel, Boston, Mass., October 15th to 17th, when technic in various sections of physiotherapy will be clinically demonstrated in the Boston City Hospital by men prominent in these departments.

CIRCUS AND SIDESHOW

A physician calls attention to the fact that the freaks exhibited in the sideshow of the traveling circus are chiefly the results of disease. He saw, among other wonders, a midget, medically known as a cretin, the result of the misbehavior of the thyroid gland; a giant, a case of acromegaly—again an effect of abnormal working of a ductless gland—the pituitary; the fat lady—due beyond question to some disturbance of one or more of these same important organs; a "wild man of Borneo" made uncanny by rickets, a disease of bad diet; an albino, due to some miscalculation on the part of Nature in proportioning the amount of coloring matter for eyes, skin, or hair; the fish man, made a curiosity by a scaly thickening of the outer layers of the skin, etc.

The doctor remarks that "a sideshow is, to a medical man, a collection of pathological and abnormal individuals which affords a more or less interesting field of study, but I raise the question, Does it seem right or decent that these unfortunate persons should be exposed to the gaze of the public and thus exploited?" We are reminded of another physician who, when asked if he did not wish to visit the sideshow, replied, "No, if you have any fine or beautiful things to show me I would be glad to see them, but I witness enough of the abnormal and ugly every day of my life."

Time was, if we can trust that terrible tale of Victor Hugo's *The Man Who Laughs,* when children were mutilated to make them money getting objects of public curiosity. These modern freaks are not intentionally produced but are due to parental ignorance or lack of medical advancement of the age in which they were born. Though they doubtless suffer little from exposure to the public gaze (and, we suspect, many of them like it) we quite agree with the doctor in wishing they were not exhibited, though we do not begrudge the general public a little normal curiosity over those specimens of Nature's waywardness which are just as strange and not more pitiful even if we know something about their cause.

As a matter of fact the public is really not much interested in these freaks for, while many glance for a moment at these specimens of what they themselves might have been, the majority do not waste their cash on the abnormals but make their way directly to the big tent where they sit for two hours or more on the most uncomfortable of seats imaginable, immensely more interested in the fine specimens of manhood and womanhood whom down in their hearts they envy. We, too, go to the circus but not to the sideshow and the expressive language of the poor deformed camel keeper in William Wilfrid Gibson's fine poem always comes to mind:

> —in the circus ring there's more delight
> Of seemly bodies, goodly in sheer health,
> Bodies trained and tuned to the perfect pitch,
> Eager, blithe, debonaire, from head to heel
> Aglow and alive in every pulse, than elsewhere
> In this machine ridden land of grimy, glum,
> Round shouldered, coughing mechanics.
>
> The only moments I've lived my life in the full
> And that live again in remembrance unfaded, are those
> When I've seen life compact in some perfect body,
> The living God made manifest to man.

Yes, the great majority who visit this perambulating Olympia, which would have made the ancient Greeks exclaim with wondering admiration, are interested in the display of body beauty and accomplishment. The sideshow takes in a few shekels, but it is only on the side and, though it may not be quite the thing to exhibit its unfortunates, the public reacts in healthy fashion, by gazing curiously, pityingly perhaps, and hastening onward to see something better than themselves, from a physical viewpoint.

We would like, however, to call attention to the sad fact that in our exploitation and our apparent enjoyment of abnormal mental conditions we are not so healthy—that we are, on the contrary, abominably vicious. Our daily papers which broadcast the performances of the sociological circus give the places of prominence in the exhibition to the abnormal—to the minute chronicling of the doings of the mentally diseased and the misbehavior of those whom insanitary social conditions have morally deformed. For the daily presentation the latest murderers, thieves (especially the big ones who steal, not from necessity), seekers after divorce, and other pathological specimens who, unfortunately, are none too

rare, are raked together from the ends of the earth for our intimate contemplation and delectation. Some of us glance hastily at the announcements of these freaks but pass quickly to the clowns who occupy the background in the funny page, or perhaps hunt for a gem of beauty in the shape of a little poem nearly lost in the nook of the big canvas but worth many times the price of admission. It is the pathological specimens, the horrible and disgusting, which are featured; the normal and fine things are merely thrown in as a sideshow.

Samuel Butler flayed us deservedly over fifty years ago, in *Erewhon,* for our attitude toward the mentally diseased and the socially deformed, and there is a faint glow of enlightenment in the cast, but so long as there is a demand for the particulars about crime and criminals and so little for details about whatsoever things are beautiful and good and true we are not making much progress toward better mental health and vigor. Time was, and not long ago, when men and women flocked to witness a hanging or a beheading. Doubtless many would do so now if they had the opportunity. They would rush also to see a highway robbery or a murder. Only a comparatively few can avail themselves of the rare treat of attending a trial, but all can see the pictures of where and how the deed was done and of the artists who took part, and they can read a carefully detailed description of just what took place on the unhappy occasion.

Both the showman and the journalist give their audiences what they want to see, but when we compare the annual presentation of the unfortunates in the sideshow of the circus with the exhibition of freaks in the daily papers, there can be no comparison of the injustice and harm done to the victims of heredity or environment who are thus held up to public scrutiny, nor is the evil, or at least lack of good, effect upon the onlookers in the two cases in the least comparable. We need to think as much of mental health as we do of bodily hygiene, and we wish that show and sideshow were as healthily proportioned in the newspaper as they are in the "greatest show on earth."

News Items.

Personal.—Dr. Henry Keller, of New York, has been appointed attending orthopedic surgeon to the Central Neurological Hospital, Department of Public Welfare, New York.

Dr. George O'Hanlon, chairman of the New York State Hospital Conference, and for fifteen years medical superintendent of Bellevue Hospital, has been appointed chief of the Jersey City Hospital, succeeding Dr. John J. Nevin.

Dr. Donald D. Van Slyke, of the Rockefeller Institute, has been honored with the degree of doctor of science by Yale University. Dr. W. J. V. Osterhout of the Institute received the same degree from Harvard.

British Medical Association Meeting.—The annual meeting of this association will be held at Southampton, England, from August 26th to September 2d.

Outpatient Service.—A pamphlet on Needs and Standards of Outpatient Service, has been issued by the Associated Outpatient Clinics of New York.

Course in Electrophysiotherapy.—Dr. Noble M. Eberhart will conduct lectures and clinics in electrophysiotherapy in Chicago, August 3rd to 8th. Information may be obtained from the McIntosh Electrical Corporation of Chicago.

Dental School at N. Y. University.—The New York College of Dentistry will become affiliated with the New York University, retaining, however, its present buildings on East Twenty-third Street.

Portrait of Harvey.—A portrait of William Harvey, painted by Van Dyck, once owned by Oliver Wendell Holmes, has been presented to Jefferson Medical College by Dr. J. Ackerman Coles, of Newark, New Jersey, in memory of his father.

Gift from Dr. Haven Emerson.—Dr. Haven Emerson, of New York, has given to the town of Southold, Long Island, a piece of land at South Harbor, near his summer nome. This is presented as a memorial to the soldiers of the town who died in the war.

Memorial to Doctor Bagg.—A tablet has been unveiled at Metropolitan Hospital, New York, in memory of the late Dr. Clinton L. Bagg. Dr. Bird S. Coler gave an address, and among other speakers were Dr. William F. Honan, Dr. C. C. Boyle, and Dr. G. F. Raynor.

Memorial Lecture. — The Fayette, Pennsylvania, County Medical Society, has voted to establish an annual scientific lecture relating to medicine, to be called the Dr. Hugh Campbell Lectures, in honor of the first graduate physician to locate in the county and also the first president of the society.

Uptown Medical Centre Association Formed.—This organization, for permanent assistance to the Presbyterian-Columbia Medical Centre, has recently been established, with Murray T. Hulbert, former president of the board of aldermen, elected as president. Dr. Louis T. Wright is secretary of the organization.

Women Physicians Meet.—The Institute Fraternity, a national organization of women physicians, recently held its twenty-first annual meeting in New York. Dr. Anna Johnson of Pittsburgh was elected president. The association operates a loan fund, through which five young women are being put through medical school.

Public Health Convention.—The first general meeting of the new Pennsylvania Public Health Association was held at Mont Alto, beginning June 22d; over three hundred were present. The following officers were elected: president, Dr. Charles H. Miner; vice-presidents, Dr. Wilmer Krusen and Dr. Carey J. Vaux, and secretary and treasurer, Dr. William C. Miller.

Dana Medal Awarded.—Dr. Edward Jackson of Denver, Colorado, editor in chief of the *American Journal of Ophthalmology,* has been awarded the Leslie Dana Medal for Prevention of Blindness. This medal, to be given yearly to a person selected by the National Committee for Prevention of Blindness in cooperation with the Missouri Commission for the Blind, was established by Mr. Leslie Dana of St. Louis, a retiring member of the Missouri Commission.

Contagious Diseases in Pittsburgh.—A report released by the Department of Public Health of Pittsburgh reports —for residents only—2360 cases of communicable diseases in May, 1925, compared with 1827, in May, 1925; but with 648 deaths in May this year and 663 in May, 1925. The main increase was in measles, of which there were 1261 cases compared with 125 in May, 1924,—and 14 deaths; also scarlet fever, in which the report is 372 cases, compared with 125 in May, 1924.

Ocean City Seashore Home for Babies.—This institution, at Ocean City, New Jersey, announces the following staff members: Medical direct, Dr. H. H. Perlman, Philadelphia; consulting pediatricians, Dr. J. P. Crozer, Dr. James McKee, and Dr. Jules Blechschmidt, of Philadelphia; visiting pediatrists, Dr. H. H. Perlman, Dr. Howard Reed, and Dr. Alvin E. Siegal, of Philadelphia, Dr. John H. Whiticar, of Ocean City, and Dr. James H. Mason, of Atlantic City; laryngologist and otologist, Dr. William H. Spencer, of Philadelphia; dentist, Dr. Walter B. Adams, of Philadelphia; chief resident physician, Dr. J. T. Doster, of Ocean City.

Book Reviews

DERMATOLOGY

An Introduction to Dermatology. By Sir Norman Walker. Eighth edition with ninety-two plates and eighty Illustrations in the Text. New York: William Wood & Co., 1925.

The popularity of this little textbook of 362 pages is shown by the fact that it has reached its eighth edition. A good deal of the text has been rewritten without enlarging the book, much of the matter relating to rare skin diseases having been omitted. The original edition is stated by the writer to have been a practical reproduction of his lectures. If the latter were anything like the text they must have been highly entertaining as well as sound and instructive. The unconscious humor of the writer is an unusual feature for a work of this kind. It is in no way undignified, however, and certainly adds to the reader's pleasure. The opinions expressed by the author are up to date and are based on many years of experience. The book is unusually well illustrated by colored plates, black and white photographs, and drawings of histological preparations. There are also a reasonable number of formulæ given in both metric systems and apothecaries measure. The book is entitled an introduction to dermatology and as such is all that could be desired. With the exception of the weight of the book which seems somewhat too great for its size the work of the publisher is excellent.

THE BEGINNING OF TUBERCULOSIS

Les Debuts de la Tuberculose Pulmonaire. By Dr. L. Ribadeau-Dumas, Médecin de la Maternité de Paris. Paris: Ernest Flammarion, 1925. Pp. 281.

This is indeed an interesting and novel contribution. Since there exists as yet no specific curative treatment for pulmonary tuberculosis, as for syphilis and malaria, for example, and since tuberculosis is at the same time perhaps the most preventable of all chronic infectious diseases, prophylaxis is the all important issue. Our studies have revealed the etiology of the disease to us very exactly, and the author justly says: "We know that tuberculosis most often begins in infancy." The methods of infection at a very early age are carefully described in the first chapters of the book, and it is pointed out that the younger the child the greater are the chances of the infection becoming active. Contrary to the belief of some authors, Ribadeau-Dumas maintains that even in very young infants the real commencement of the disease and the seat of pathological lesions are to be traced to the lungs.

This little book has no other ambition than to familiarize the general practitioner with the method of immunizing the infant suspected of tuberculosis at the earliest possible period. In this he follows the footsteps of Calmette, Guerin and Weill-Hallé. He prescribes for the infant two milligrams of the bacillus BCG at three different periods during the first nine days of its life; that is to say, on the third, fifth and seventh, or the fifth, seventh and ninth days. He instructs the nurse to give these two milligrams on those days half an hour before she puts the child to the breast of the mother. It is desirable that the stomach be as near empty as possible for the administration of the bacilli. This method of immunizing has proved to be without danger or complication, but the vaccination should of course never be performed without the consent of the parents. The experiments have been controlled with the help of cutaneous reactions and showed, after injection, 88.7 per cent. of cases negative and 11.3 per cent. positive. It would seem that unless the tuberculous mother is willing that the child should be taken from her immediately after confinement, this method would give the greatest possible chance of safeguarding it against the development of tuberculosis. If this immunization of the suspected infant should prove to be in the long run what the authors of the method claim for it, we may look for a still greater reduction in the morbidity and mortality of tuberculosis than we have already obtained.

SYPHILIS

Modern Aspects of Syphilis. By M. J. Horgan, B.A., M.B., B.Ch., B.A.O., N.U.I. London: Henry Frowde and Hodder & Stoughton, 1924. Pp. 136.

In this highly practical little volume the author has gathered together the latest views concerning the nature of syphilis and its treatment, based on the lectures of Kyrle, of the Vienna school, including the study of the cerebrospinal fluid and the case sheets of patients in Finger's clinic.

In the foreword, written by Finger, he emphasizes the fact that his clinical teachings are distinguished more than anything else by the stress laid on the relations of the cerebrospinal fluid in syphilis. The volume under review strongly corroborates this statement. The major part of the book is devoted to this subject. In point of fact, the key to the successful understanding and treatment of the disease is declared to be found in a thorough study of the spinal fluid and its treatment.

There are excellent chapters on the pathology of syphilis, in which it is emphasized that the treponema is not a blood parasite but a tissue parasite; that the tissues of the body are quickly invaded, and that the blood merely acts as a medium for the infecting organism to reach the tissues, where proliferation takes place and anchoring of the parasite occurs. Because of this, Finger holds that the blood Wassermann is of secondary importance as compared with the spinal liquor reaction. The liquor should be tested at various times during the treatment, and in all cases there should be a systematic search for liquor changes in the second or third year of the disease.

Salvarsan and mercury continue to be the mainstay of treatment, but they should be administered in adequate amount. Where salvarsan cannot be given in full doses and over an extensive period, it is advised that older methods be adhered to. No salvarsan treatment is considered better and safer than treatment with half courses and "chopped up" courses of salvarsan.

The author stresses the importance of the body resistance to the invading organism, as an important factor that must be reckoned with at all times. To increase this resistance various methods are dis-

cussed, particularly Kyrle's method of nonspecific therapy, in which injections of milk are employed. These are considered valuable adjuncts to the regular treatment. A two per cent. iodine preparation (mirion) is recommended for the same purpose. The malaria treatment in conjunction with specific remedies is advocated for late syphilitic manifestations; and it is stated that Kyrle is achieving gratifying results in the treatment of early syphilis by a combination of malaria and specific therapy.

The simultaneous intravenous injection of salvarsan and a one per cent. solution of corrosive sublimate (Linser's method) is highly recommended for the simultaneous administration of salvarsan and mercury. It is said to be highly effective and never inconveniences the patient.

Typographically the volume is all that could be desired. It may be said to be unique in that it presents no illustrations, something to be grateful for at times. It is a most interesting and useful work.

La Sifilide ignorata e strana. Seconda Edizione con figure e tavole a colori. By Prof. Carlo Martelli, Docente di Anatomia Patologica e Clinica Medica nella Università di Napoli. Napoli, Casa Editrice Libraria Vittorio Idelson, 1923. Pp. xxiii, 642.

The second edition of this authoritative work sets forth in a very full and clearly arranged manner the many forms in which syphilis reveals its invasion of the organism. It discusses with particular emphasis those concealed and mistaken inroads which do not appear under the typically accepted manifestations. It reviews the pathology of the disease, its general pathogenesis, and deals with the authority of wide experience with the question of immediate diagnosis and treatment of the primary illness and then the necessity of determining in which of the many possible directions the patient may show tendency to further effect of the infection. The treatment must not be chosen or followed arbitrarily but with a watchful heed to the indications of the particular case and to the particular form of manifestation. None of the widely extended ravages which the disease may make upon the organism, direct or indirect, through heredity or as a secondary, tertiary, quaternary development, is permitted to escape discussion. A full bibliography of contemporary authorities is appended.

HEREDITY

The Inheritance of Mental Diseases. By Abraham Myerson, Professor of Neurology, Tufts College Medical School. Baltimore: Williams & Wilkins Company, 1925. Pp. 336.

The spirit of the author of this book has led him into a method of presentation that makes controversy a truly scientific exercise. He has fearlessly attacked old favored conceptions and yet always with a candid apology for any undue harshness and an absence of dogmatic conviction in his own views. His exposure of the hollowness of the insanity fiction and his redefining of psychiatry to show that it is not exclusively a science of mental diseases, are examples of the service he renders merely in clearing away the heavy mists which prevent correct thinking. In his further attack upon the acceptance of the concept of heredity, especially in relation to mental diseases, and upon the type of work set forth to uphold it, there is room for agreement or disagreement. Therefore the author's method of detailed investigation, the use of actual clinical material, cited with judicious conservatism in illustration and interpretation, his attempt to break up the misleading grouping of facts by homogeneous abstractions instead of by examining them in all the differences of varied manifestation, mental and physical; these all enlist the reader's own spirit of actual inquiry and offer a challenge in the face of his too ready acceptance of ideas long handed on and seemingly supported by a mass of data. Much of the latter Myerson believes unscientifically collected and applied. Moreover, the data are used to uphold a conception of heredity which has artificially isolated the word from the facts of medicine. It has not regarded the varieties of manifestation arising out of many causes, largely exogeneous, which cannot be grouped together on one basis of "neuropathic constitution" or what not. The facts which Myerson brings forward show such a range of incidence, even of definite disease entities, that the assumption of hereditary derivation from neuropathic stocks finds little ground. Transmission of mental disease from generation to generation he does not deny; his emphasis, however, is upon blastophoria, or injury to the germ plasm, an environmental phenomenon, which is transmitted and may tend in either direction, that of betterment and disappearance of the injury or that of deterioration and extinction of the stock.

SURGICAL CLINICS

The Surgical Clinics of North America. Volume IV, No. 6, December, 1924. Clinic of Frank H. Lahey, M.D., Boston. Index Number. Volume V, No. 1, February, 1925. New York Number. Philadelphia and London: W. B. Saunders Company, 1925.

The Lahey clinic number of this series of well known publications covers the ground of toxic goitre most thoroughly. Of the seventeen clinics presented in this volume, by eight authors, eleven are devoted to the subject of the thyroid, its surgery and its complications. Dr. Lahey himself contributes six very interesting clinics, ranging from the evolution of a thyroid clinic to the treatment of duodenal fistulæ by suction.

The multiple stage procedures, the plan which has been adopted by Dr. Lahey and his associates, are fully detailed and explained. These procedures consist of various steps or blocks, each of which may be considered a measure of progress, and each to be completed in the doubtful cases as a single procedure. The next step is taken only after the effect of the first has been noted and the probable effect of an advance through the next block seriously considered. The patient is returned to bed, the effect noted, and if the reaction be not unduly severe, the next step is completed within two or three days. Seven steps or blocks in the road towards subtotal thyroidectomy are thus outlined and fully described.

In support of these "block" procedures, it is stated that during the past three years a total of 1,376 operations have been performed on 976 patients at the clinic, with but seven deaths. In a group of 1,258 cases in which operation was performed, 583 were primary hyperthyroidism with a mortality of 1.7 per cent.; 320 were secondary hyperthyroidism, with a mortality of 2.1 per cent.; and the remainder were

nontoxic goitre, with a mortality of 0.51 per cent. The physician or surgeon interested in goitre will do well to study this interesting volume.

The New York number offers thirty-five clinics by thirteen well known New York physicians and surgeons. The subjects treated have a wide range. The first clinic is by Pool on exophthalmic goitre, followed by an excellent clinic on the surgical cure of gastric and duodenal ulcer by Berg, of Mount Sinai; Beer, of the same hospital, contributes a series of interesting articles, mostly urological in character, with a demonstration by Edelman, one of his associates; Furniss presents the subject of urinary incontinence in women, and Wood, of St. Luke's, offers a survey of röntgen therapy. Lilienthal's dry clinic on surgical diseases of the thorax is extremely interesting; one of his cases is that of cervical sympathectomy for angina pectoris, and while the end result is still uncertain, both patient and surgeon appear to be hopeful of lasting benefit.

The volume presents the usually attractive form and constitutes an invaluable addition to the long list of volumes which have preceded it in the series of *Surgical Clinics.*

ENVIRONMENT AND GENIUS

The Constant Nymph. By Margaret Kennedy. Garden City: Doubleday, Page & Co., 1925. Pp. 344.

The language of music is not so different from the speech of other muses. At least, Miss Kennedy permits it to ring with utmost clarity and comprehension to both lay and professional minds. And the psychology of the musician is comparable, for all his sought after individuality, to the psychology of most creative thinkers.

The story of *The Constant Nymph* shows primarily the struggle on the part of creative effort to establish its "difference," its genius, its isolated significance. There is a beautiful picture of the seething unbalance between childlike reaction to the world's laws, and mature production of a man's finest work. This lack of inner harmony is a recognized earmark of art in every form. An artist has something to say. The secret turmoil makes the need of expressing himself greater. As yet no novelist has pictured the coordinated artist. His productivity would be unbelievable, inhuman. More people than not have little to say. The artist is after all but a human brother. He must pay, to interest the reader, a heavy price of conflict for his intellectual, creative superiority.

Sanger is the type composer, immense, volcanic, unrepressed, a secret worshipper of his own genius. Not that that detracts from the genius in any way. It merely allows him to do as he likes quite childishly. He has irresponsibly accumulated a family. He dies, leaving the family destitute. Relatives, plans, the outside world, rush in to tamper as they love to do with the property of a great man. Necessary of course—the children are under age. In marvellously sensitive fashion the ordering of Sanger's children's lives is laid bare, the constant "it is for the best" dogma of the bourgeoisie running counter to every known law of personality and promise. Sanger escaped the mob; his gifted children shall be made to pay!

The most gifted of all is Tessa, in that she is not overdeveloped on any one side. Naturally her struggle is the greatest. The others, even as children, have some strong bent that will lead them in spite of themselves. Tessa, at sixteen, is a vibrant human being, faced with the necessity of annihilating her personality. Tessa's genius is for living, and she is not allowed to live.

Further complications of the plot. Lewis Dodd, the musician whom Tessa has loved since childhood, marries the distant cousin who makes it her mission to "bring up" the Sanger children. She is always "bringing up" someone or something. Like most uplifters she is convinced of her altruistic aims, whereas selfglorification is at the root of her whole hard being. A purely noncreative force bearing down with merciless concentration on two productive beings; the result, an intolerable situation that resolves itself tragically and truthfully.

Of the writing of the book little need be said. It speaks for itself—it is wholly unobtrusive, one absorbs rather than reads, one hears and lives and feels, rather than sees. *The Constant Nymph* pictures life —for the moment in a musical circle—as fascinating, as terrible, as blindly carefree and selfish as life really is. While for our comfort we are permitted to reason that this is not necessarily your life or mine, but nevertheless some slice of life worthy of sympathy and recognition.

FICTION BY A PHYSICIAN

Sea Horses. By Francis Brett Young. New York: Alfred A. Knopf, 1925. Pp. 321.

Francis Brett Young has given us refreshing fare in novel forms before. His last book is no exception. He seems to delight in choosing time and place for his dramas quite out of accord with regulation. A sea voyage to an African port, a woman and child taken out of pity as passengers on a cargo vessel, a mysterious goal! All quite enough to keep captain and crew unrestful. They arrive. Instead of resolving themselves, the mysteries grow more impenetrable. Life moves in a sort of miasmic haze. Vast gestures are made under circumstances so sordid and dispiriting that they are not gestures any longer but reflexes of discomfort. There is endless traffic back and forth from the town to the swamp where the woman's husband lives. Each time it is the same, hideous. Each time it is more overwhelmingly different. Some hint of an extrahuman power breathes over the landscape—an atmospheric dragon, a cosmos living, acting, regardless of our infinitesmal cosmos. The dragon rumbles, flicks his tail, knocking the groves pell mell, belches, goes on about his business. On the graceful ship the tiny puppets push on with their loves, their torments, the intrigue of the harbor town. The war reaches its crisis, the atmosphere begins to vomit trouble and the beautiful ship stealing out of the maws of the *Caballos de Marinhos,* the dread Sea Horses that guard the roadstead, runs aground. These little humans are too annoying! The dragon is sick of them. A lurch, a shrug, the story ends.

Sea Horses has vigor, novelty. It is thoroughly well done. Francis Bret Young in his personal reaction to his medium has again achieved originality.

Medicoliterary Notes.

Mussolini, the Italian dictator, is now reported to be writing a play, which he has asked a leading actress to produce in America. If this is true, it adds one more accomplishment to the long list of those of the versatile statesman, who, it is said, is an able player of the violin, has written a novel, attained success as a journalist, and has played parts in private theatrical performances.

* * *

If there is anywhere in the world an exception to the rule that people get the government they deserve, it is surely to be found in China. There, while the people have cultivated for centuries a natural genius for the arts of peace, the government has been frequently incompetent beyond the nightmare dreams of the West. General Hsu, the leader of a mission sent over by the present Peking government to examine European and American ways, puts forward a quaint new explanation of this paradox. He complains that cabinet meetings in earlier times were held at daybreak, whereas now they are only held as late as noon. Perhaps if the rival soldiers who now dispute for supremacy in China could be brought together at dawn, they might reach some agreement helpful to the country.—*Manchester Guardian Weekly.*

Announcement has recently been made that the Physicians and Surgeons Book Company, publishers of medical works, is about to enter the field of general literature and has formed for this purpose a subsidiary company to be known as the Capitol Book Company. The first publication of the new company is the novel of James Clark Bennett entitled *Shedding the Years,* described as "a thrilling tale of modern life and rejuvenation."

* * *

That bees may be relied upon to do the work of constables, and do it efficiently, was shown the other day at a village inn in Prohnsdorf, Prussia. When a free-for-all fight developed among the patrons, with amateur pugilists belaboring each other, the landlord, to save his tables and chairs from being smashed, rushed out and brought back a beehive. After putting on a mask he released the bees. The industrious insects did their work swiftly and thoroughly, and within a minute every one of the combatants had fled from the battlefield.—*New York Times.*

The column, Notes for Bibliophiles, edited by Leonard Mackail for Books, literary supplement of the *Herald Tribune,* contains in the issue for June 28th an interesting article on Dr. John Shaw Billings. The information is based on two lives of Dr. Billings, namely, that by Dr. Fielding H. Garrison entitled *John Shaw Billings, a Memoir,* and the recent book by Henry M. Lydenburg, chief reference librarian of the New York Public Library, entitled *John Shaw Billings, Creator of the National Medical Library, and Its Catalogue, First Director of the New York Public Library.*

* * *

The mental health survey of Staten Island, conducted by the National Committee for Mental Hygiene, has recently been completed and an outline report is given in the issue for May of the *Mental Hygiene Bulletin.* Some of the outstanding features of the survey were the discovery of the large number of children in need of mental hygiene service, the inaccessibility of facilities for the treatment of mental health problems, and the discovery of what seems to be a thyroid district that is dependent upon the local water supply.

* * *

Another announcement of interest in this issue of the *Bulletin* is that of the opening of a demonstration child guidance clinic in Philadelphia. The quarters now occupied by the clinic staff consist of a completely renovated three story house owned by and adjoining the Children's Hospital. This hospital is cooperating closely with the clinic and will furnish medical and laboratory facilities for the clinic's patients. The demonstration was invited to Philadelphia by the All-Philadelphia Child Guidance Clinic Committee, of which Dr. Charles H. Frazier is chairman.

On May 5th the famous old Italian University of Pavia, probably the oldest college in the world, celebrated its eleventh centenary of the primacy over other scholastic institutions in Italy awarded it by Lothaire, grandson of Charlemagne, in 825 A.D. Names famous in the history of medicine connected with this institution are those of Antonio Guancaio, Giovanni Matteo Ferrari, and Girolamo Cardano, philosopher as well as physician.

* * *

The *Yale Review* for July has some excellent articles, among them one by Elmer Edgar Stoll entitled Of Dogs. Mr. Stoll sings the praises of dogs in general and in particular of the bright little Maltese terriers. Other interesting features are The Connoisseur, by Walter de la Mare; War Risks in Economic Conflicts, by Sir Arthur Salter; Law and Literature, by Benjamin N. Cardozo; Charlotte and Emily Brontë, by Herbert Read; Sex and Genius, by Alice Beal Parson; and New Letters About Poe, edited by Stanley T. Williams.

* * *

The British press announces that Sir James Barrie has prepared with great pains a film version of his play, *A Kiss for Cinderella,* and has again cast Betty Bronson, the screen Peter Pan, for the leading part. It is estimated that it will take several months to complete the film. *Dear Brutus* is also being prepared for the movies.

* * *

A campaign to prevent accidents to children has recently been inaugurated by the American Museum of Safety in cooperation with the New York State Department of Labor and the Board of Education. These agencies will work chiefly through the heads of the evening and continuation schools. The campaign is the result of a report by the State Department of Labor showing that in one year 1,983 children were seriously injured while at work in New York factories.

* * *

One of the leading features of the *North American Review* for June-July-August is a symposium on Five Years of Prohibition and Its Results. The discussion is carried on by William H. Sayton, Henry Samuel Priest, George Gordon Battle, Henry Bourne Joy, James P. Holland, Dr. Charles L. Dana, Oscar Terry Crosby, Samuel Harden Church, Lawson Purdy, and John Philip Hill. All are opponents of prohibition. In the next issue of the *Review* will be a symposium presenting the opposite side. Other features of interest are Reminiscences of Huxley, by Henry Fairfield Osborn, and The Future of Leprosy, by Dr. Victor G. Heiser.

* * *

Good books for summer reading are *St. Mawr,* the story of a stallion, by D. H. Lawrence (Knopf); *Stolen Idols,* a mystery tale by E. Phillips Oppenheim (Little, Brown); *Sea Horses* by Frances Brett Young, a romance of the sea and Africa; *The George and the Crown,* one of Sheila Kaye-Smith's Sussex tales; *The Constant Nymph,* by Margaret Kennedy, "the most popular novel of the year"; *Mrs. Dalloway,* by Virginia Woolf, a story of life in London; *The Mother's Recompense,* by Edith Wharton, in the authors usual style; *The Great Galsby,* by F. Scott Fitzgerald, the story of an attractive, mysterious young man of great wealth who keeps open house; *In Zanzibar,* by the late Ralph D. Paine, the story of one thrilling night and the crew of a U. S. cruiser; *The Carolinian,* by Rafael Sabatini, an adventure story of the time of the American Revolution; *Thus Far,* a mystery tale by J. C. Snaith; another by Caroline Wells, *Face Cards;* others, *The Seine Mystery* by Cleveland Moffett, the *Mystery of Redmarsh Farm* by Archibald Marshall, *The Uninvited Guests* by J. Jefferson Farjeon, *The Annexation Society* by J. S. Fletcher, *The Missing Initial* by Natalie Sumner Lincoln, *Black Shirt* by Bruce Graeme, *The Red Lamp* by Mary Roberts Rinehart, and *Afterwards* by Mrs. Belloc Lowndes. For pure fun read Webster's *Poker Book, Here Comes the Bride* by Irvin S. Cobb, *Bigger and Blacker* by Roy Octavius Cohen, *The Crazy Fool* by Donald Ogden Stewart, *What of It?* by Ring Lardner, and *The Glimerick Book* by Shaemas J. A. Witherspoon. For travel choose *So You're Going to Italy* by Clare E. Laughlin, *Carpenter's World Travels* by Frank G. Carpenter. *The Adventure of Wrangel Island* by Vilhjalmur Stefansson, *The Lost Oases* by A. M. Hassanein Bey, and *Six Years in the Malay Jungle* by Carveth Wells.

Abstracts from Current Literature

DERMATOLOGY AND SYPHILOLOGY

Malaria Treatment of Syphilis.—J. Kyrle (*Wiener klinische Wochenschrift,* October 23, 1924) observed some excellent results in the malaria treatment of cases of latent syphilis with cerebrospinal fluid changes. Although not all the pathological cerebrospinal fluids in chronic cases could be brought to normal, the lymphocytosis could usually be made to disappear. No failures were observed when the treatment was instituted within a year of the infection. Of 205 patients treated with one course of arsphenamine malaria arsphenamine treatment, clinical recurrences were observed in only three. Treatment was given also when the cerebrospinal fluid was normal. The author found the results with one such course of treatment superior to all other forms of treatment.

The technic is as follows: A course of 3.0 grams of neoarsphenamine within four weeks is followed by the malaria treatment. During or after the eleventh week, 0.5 gram of quinine is given intravenously, and this dose is repeated in eight hours. On the following day, 0.45 gram of neoarsphenamine is given, and within the next twenty-four hours this is followed by two injections of quinine, eight hours apart. The treatment is then continued with neoarsphenamine, again giving 3.0 grams in four weeks.

Even though two patients died, the author does not consider heart disease a contraindication. The patients, however, should be selected. No recurrences of malaria were observed. It appears that patients who are intolerant to arsphenamine before being infected with malaria, are more tolerant of it afterward.

Antiseptic Lotions, Baths and Dressings in Skin Disorders.—F. Babzer (*Paris médical,* February 28, 1925) asserts that antiseptic lotions may be of marked prophylactic as well as curative value in numerous skin affections. In the various eruptions of pyogenic origin, lotions of potassium permanganate, zinc or copper sulphate, or mercury bichloride, often are decisive in their effects. Recurring furunculosis is checked by repeated antiseptic applications to the skin. Dressings with relatively strong—one or two per cent.—solutions of permanganate are useful in infected lupus. In extensive chronic eczema, scaly and itching, in which secondary pyogenic infection always exists, as well as in seborrhea and seborrheic or mycotic eczema, one or more weak permanganate baths afford marked relief and facilitate the action of the other topical medication employed. In psoriasis, occasional disinfecting baths are useful chiefly to prevent the pyogenic dermatitis which sometimes proves disturbing during treatment with oil of cade or other tar preparations. During mercurial or arsenical treatment in general there arise erythemas and erythrodermias, primary or secondary, which are often accompanied by various kinds of pyogenic lesions, arising either through added local infection or from the germs already at the skin surface previous to the onset of the erythema. This complication may so progress as to produce serious cachexia and even death. There is therefore great advantage in the use of permanganate baths from the onset of the erythrodermia, to prevent the more or less obstinate and serious pyogenic complication. The baths are also of curative value. In the intervals between them the aim should be to dry out the epidermis with, e.g., a mixed powder of talcum and zinc oxide. In exfoliative dermatitis of the new born, as well as in that of adults, antiseptic baths are useful; in obstinate cases, permanganate baths may be alternated with oak bark baths. In bullous skin disorders with secondary infection the antiseptic solutions used should be weak; in severe bullous cases, simple baths containing a decoction of oak bark—one kilogram to the bath—or with tannic acid may be used alone. In some forms of pruritus, notably the senile type, a bath containing sodium silicate may be ordered. In various other itching skin affections a bath to which one or two teaspoonfuls of an alcoholic menthol solution have been added is indicated both for antisepsis and to relieve the itching; with it may be combined a bath containing a few teaspoonfuls of spirit of camphor. In a case of acute generalized lichen the author had success with an emulsion of cod liver oil—100 grams added to the bath. In frost bite immersion in a two to five per cent. solution of calcium chloride has been recommended.

Syphilis as a Cause of Delayed Resolution in Pneumonia.—Thomas Fitz-Hugh, Jr. (*Medical Clinics of North America,* November, 1924) emphasizes the following points:

1. Syphilis is an important cause of what clinically is delayed resolution of acute pneumonia. It is more frequent than is generally recognized, and deserves a place in our textbooks along with effusion, empyema, lung abscess, pulmonary tuberculosis, and the other well known complications and sequelæ of pneumonia.

2. The report of a positive Wassermann test, made by a competent serologist, is indicative of syphilis even when the blood is tested during the course of an acute pneumonia. But a patient may have syphilis and empyema too.

3. A pneumonia patient, whose febrile illness is unduly prolonged by persistence of pulmonary pathology and in whose case empyema, abscess, and tuberculosis can be reasonably well excluded, should have the benefit of a Wassermann test. If this is positive the patient should have vigorous antiluetic treatment. The therapeutic test completes the diagnosis, from a practical point of view at least.

4. In addition to the "diagnosis by exclusion," supplemented by the Wassermann test and the therapeutic test, the complete diagnosis would seem to be suggested by the following: Rapidly changing physical signs elicited over the involved lung tissue, which one day might seem to be the site of massive effusion and the next day clearly in a state of marked consolidation with loud tubular breathing and succulent râles; evidence of visceral syphilis in other organs, e.g., an unduly enlarged and tender liver; history indicative of syphilis; the x ray picture.

5. Finally it is suggested that if syphilis is constantly borne in mind by all who have to treat pneumonia, this complication will be recognized and combatted at an early stage, when gratifying results can be obtained. It seems probable that by early treatment of this form of delayed resolution some patients will be spared the indelible lung scars that in after years would surely be dubbed syphilis of the lung.

Treatment of Psoriasis.—Leo Kumer (*Wiener klinische Wochenscrift,* September 4, 1924) states that the various forms of psoriasis and their special localizations require an individualizing treatment.

The most severe form, the universal psoriasis, requires the mildest form of therapy. The author places such patients in a water bath to which is added in the beginning redium emanation in a high dose (500,000 Mache units); it is surprising how rapidly the symptoms disappear with this measure. As soon as improvement is observed, the further progress is aided by the addition of Vleminckx's solution in small doses (10 to 150 gm.). Of salves, only the indifferent unguentum simplex or a weak sulphur vaseline is indicated in the severe form.

In all acute cases still in the progressive stage (those showing small single efflorescences, only the centers of which are covered by scales) the best results are obtained at first with the most bland form of therapy, such as baths and sulphur salves. Arsenic, particularly is contraindicated in such cases.

Stationary, inveterate foci require tar bath and pyrogallic and salve treatment, or chrysarobin, and if this is not successful roentgenotherapy should be tried. Internal treatment, with remedies that are not always entirely harmless to the organism, is indicated only in exceptional cases. Psoriasis of the hairy parts disappear rapidly; treatment with five per cent. white precipitate or sulphur salve is usually sufficient, but with very extensive areas, with marked deposition of scales, as in universal psoriasis, a preliminary application of oil for the removal of the scales is helpful. The areas on the face also react favorably to a mild therapy. In contrast to this is psoriasis of the hands and feet and also the isolated areas on the knees, the elbows and over the sacrun, which are very obstinate and require energetic treatment. These cases respond very well to the painting of such areas with concentrated oleum rusci and a covering with a ten per cent. salicylic acid soap plaster, followed by a second application in two to four days. This form of treatment is also indicated in the extraordinarily obstinate psoriasis of the nail; if it fails, radium irradiation should be tried.

Formaldehyde in Epithelioma of the Face.—O. Laurent (*Bulletin de l'Académie de médecine,* January 20, 1925) recommends formaldehyde injections in cases of epithelioma of the face in which operation is deemed too mutilating and radiation fails. Three patients thus treated fourteen years ago are still living. One had a vegetant epithelioma involving almost the whole of the left side of the nose up to the eyelid, and healed in three months under the formaldehyde treatment. In another, a third of the lower lid had been eaten away, but complete healing gradually took place under formaldehyde, although the lesion had been resistant to radiation. Two more recent cases had had four radiation treatments without benefit, but formaldehyde healed them in eight weeks. A radiologist found the remedy valuable for fissures and scabs on his hands. The drug is injected at various points at the base of the diseased area, one drop at each point, or sometimes applied directly. In early cases a single treatment may suffice. Practice with the procedure makes it possible to limit the necrobiosis to a minimum, i.e., to a scab covering the ulcer, and thus at times to procure healing more rapidly than by radiation. As the drug does not have the selective properties of radiation, no marked differences in its curative effects were noted between precancerous lesions, senile keratosis, senile multiple epitheliomatosis, flat cicatricial epithelioma, spinecelled epithelioma and rodent ulcer. The drug is, in the first place, bactericidal; it also fixes and mumifies the protoplasm and, in particular, the nuclei undergoing mitosis; it tends to vitalize the connective tissues, impaired by the malignant growth, and probably also to vitalize the epidermis. In addition, it induces a phagocytic reaction, powerful or slight according to the amount used.

Erysipelas Successfully Cured by Subcutaneous Injection of Cow's Milk.—Thomas A. Lebbetter (*Canadian Medical Association Journal,* December 1924) presents the following summary of his paper: The rise in the temperature which follows the injection of cow's milk possesses a curative effect in the treatment of erysipelas. Antistreptococcic serum is expensive, uncertain in its action and not always available for immediate administration. Besides, to get the full effect of this particular method of treatment one needs to give concurrently an autogenous vaccine which is difficult to procure without considerable delay. Foreign protein (cow's milk) is cheap, simple to prepare, and within the immediate reach of every general practitioner. It eliminates the delay of waiting to procure serum and autogenous vaccines and facilitates a rapid uninterrupted recovery. It has proved in our experience a rapid economical and positive factor in the immediate cure of erysipelas. In the twelve cases treated of the eleven patients who had been seen early before the fifth to the seventh day of the disease, four had the temperature reduced to normal and all other symptoms arrested within twenty-four hours of the first injection; four had the temperature reduced to normal and all other symptoms arrested within forty-eight hours of the first injection; and three had normal temperature and all other symptoms arrested within seventy-two hours of the first injection of the foreign protein.

Seborrhoic Dermatitis.—Herman Goodman in his article entitled, "Loss of Hair from Common Causes," recently published in the *Boston Medical and Surgical Journal,* discusses the etiology and appearance of seborrhoic dermatitis. He writes that the condition may develop from other apparently milder forms of scaling of the scalp. The condition of the scales and the underlying scalp may not appear very much different in eczema seborrhoicum than in pityriasis steatoides, but the presence of a similar more or less superficial red scaly greasy condition of the skin distant from the scalp, in favored locations, as the middle of the chest and back, and the flexors, leads to the diagnosis of the seborrhoic condition rather than the pityriasis. The lesions of the skin may be attributed to chance infection from the groups of organisms affecting the scalp, but unless the soil is favorable seborrhoic eczema does not develop. In this condition, as with practically all the others considered, the general condition of the patient cannot and must not be overlooked in consideration of the treatment of his affection. A trip to the country for city people, relief from tight or ill fitting hat gear, diet, exercise, all have their place in the therapy. A review of the chemical constituents of the blood or urine may reveal a fault of the organism, the correction of which gives relief. Seborrhoic eczema certainly and surely leads to loss of hair. Ordinarily much worse in men, and usually, in the early years of adult activity, seborrhoic eczema untreated, or even treated, causes the loss of hair typified by the extraordinarily high forehead and the fringe over the ears. Incidentally, when the hairs have all gone, the seborrhoea goes with them, as far as the scalp is concerned. Baby or lanugo hairs may take the place of the adult or true hairs which have fallen, but this should not be taken as a good sign prognosticating the return of adult hairs. Rather, the reverse should be feared. According to living habits, occupation, etc., the condition of the skin associated with eczema seborrhoicum of the scalp may be evanescent or persistent; easily eradicated, or resistant to therapy.

Hop Dermatitis.—W. J. O'Donovan (*Lancet,* September 20, 1924) states that in a characteristic case of plant poisoning the hands, face, and genitals are covered with closely placed minute vesicles and bullæ on an erythematous base. There is often considerable tumefaction. The eruption is often mistaken for erysipelas, but its appearance in gardeners should lead to careful inquiry as to the possibility of plant poisoning. Females only, so far, have been affected, from the ages of twelve up to sixty-seven, always in the month of September. The eruption is severe and recurs rapidly on reexposure. The diagnoses that have been so far suggested, before the occupational etiology was appreciated, were impetigo, erysipelas, hydroa, and urticaria.

A Clinical and Experimental Investigation of Arsphenamine Poisoning.—Soma Weiss (*Proceedings of the New York Pathological Society,* January-May, 1924) used cats to study the gross and microscopic tissue changes produced in the liver, spleen, and kidneys by arsphenamine, by arsphenamine combined with mercuric salicylate, and by arsphenamine administered after chloroform. Repeated doses of arsphenamine, corresponding to massive therapeutic doses, produce small areas of necrosis, fatty infiltration, congestion with round cell infiltration, and occasionally cloudy swelling in the liver cells, with the evidence of fatty degeneration in the tubules of the kidneys in some cases. The poison produced no changes in the spleen. The tissue injury was not increased or modified when arsphenamine was combined with mercuric salicylate, in amounts corresponding to therapeutic doses in man. When the doses of arsphenamine mentioned were administered to cats in which liver injury had been produced by chloroform, the liver regenerated at the same rate as that in the series of cats which received chloroform alone. Arsphenamine, therefore, does not appear to increase the injury produced by chloroform. The histological changes and the behavior of the poisoned animals did not correspond to those observed in acute yellow atrophy of the liver in man. In twenty-one of twenty-nine human fatalities due to arsphenamine, death followed the injection of the drug in a few hours. In seventeen cases in which autopsy was performed, the liver showed no pathological changes, but the cases all showed severe chronic pathological changes in other organis. It is concluded on the basis of these studies that the majority of fatal accidents can be prevented by observing caution in individuals who show cardiovascular and renal disease, clinical evidence of status lymphaticus, or acute infectious disease (pneumonia). Acute yellow atrophy of the liver cannot be attributed to a direct toxic effect of arsphenamine. However, as the close relationship between its administration and acute yellow atrophy is definite, the conclusion that arsphenamine plays an indirect rôle in causing acute yellow atrophy is inevitable.

Infantile Roseola.—Paul W. Beaven (*Archives of Pediatrics,* October, 1924) reports five cases of infantile roseola. This illness differs from the known exanthemata in that it is apparently noncontagious. Another cardinal point is the age incidence. In all of the cases reported, practically every one has occurred between the ninth month and the beginning of the second year. It also differs from all other exanthemata in that the defervescence is by crisis and has the further peculiarity that the crisis is attended by a typical eruption.

The onset is abrupt, with fever. The temperature is sustained for four days and is usually high. During this period there is nothing to explain the fever. The tonsils or pharynx may be red, and there may be a slight cough, but the lungs, ears and urine are negative. Leucopenia has been reported. Urine examinations are negative throughout. The temperature uniformly falls to normal on the fourth day and the rash then appears, usually first on the trunk. In a few hours, generally twelve to sixteen,

the eruption has reached its height. It covers the whole body, but the abdomen and upper chest and shoulders and neck are chiefly affected. Relatively few lesions are found on the face and extremities. The separate lesion is a pale rose red or slightly pinkish macule or maculopapule about 0.5 cm. in diameter. Usually in twenty-four hours after the height of the rash is reached, the eruption has entirely disappeared. Occasionally there is desquamation. There are no complications.

The differential diagnosis includes German measles, scarlet fever, drug eruptions and food idiosyncrasy. There is little doubt but that this syndrome is a clinical entity and should be so recognized. It is probable that the disease has existed for a number of years, but that it has been classed among the unexplainable eruptions of infancy.

GENECOLOGY AND OBSTETRICS

Dysmenorrhea in Young Women.—A. E. Sanderson (*British Medical Journal,* September 27, 1924) applies the term "dysmenorrhea" when menstruation is attended by any kind of suffering on the part of the woman; normal menstruation is not associated with any symptoms. Of 2,050 girls questioned seventy eight per cent said they were normal, and twenty two per cent had various degrees of dysmenorrhea. In only five cases was spasmodic dysmenorrhea encountered.

It is generally believed that during the period of menstruation all forms of bodily exercise and bathing should be interdicted. The author believes that this is erroneous and that exercise and bathing should be carried on daily just as at other times. In fact, exercise will usually relieve such discomforts, and a period of inactivity even aggravates the symptoms. The baths should be the usual warm bath, but not cold douches or swimming. Athletic games, such as hockey, lacrosse, cricket, tennis, drilling, gymnastics, riding, cycling, or dancing should be continued throughout menstruation. Constipation should be combatted at this time. The continuance of bodily activity throughout menstruation is an excellent way of preventing dysmenorrhea.

Not only is exercise prophylactic against dysmenorrhea, but in most cases it can be even cured by exercise in cases where the dysmenorrhea has already existed for some time. Operation should not be performed, nor even suggested to the patient, until baths and exercise and drugs have been tried for at least six months and found useless. The treatment is largely a matter of building up the general health of the patient. Active, outdoor life is not always prophylactic against dysmenorrhea unless the activity is continued during the period.

The drug most usually prescribed has been ammonol. Extracts of ductless glands were not prescribed for dysmenorrhea itself, apart from abnormal periodicity, or flow, or other symptoms indicating disorder of endocrine secretion. In eleven successful cases small doses of thyroid extract, and in three cases a polyglandular preparation were given.

Dysmenorrhea in Young Women.—Leonard Phillips (*British Medical Journal,* September 27, 1924) observed about four hundred women without physical signs. All of these women had very definite and disabling pain, and all had been treated unsuccessfully by medical measures. An analysis of these cases shows the following points of interest:

The majority of the patients lead inactive lives and in one half of them constipation is a definite complaint. One third of the patients were poorly developed, with weak abdominal musculature, faulty posture and breathing, anemia and visceroptosis—the class so much improved by hygienic treatment. The variations in the site, time, duration, and character of the pain are very great, and, together with varied general conditions and local findings, suggest the possibility of several causative factors in dysmenorrhea, even though gross pelvic physical signs are usually absent.

Intrinsic dysmenorrhea begins at puberty and recurs at each subsequent menstruation. In some instances this is the case, but in a great number of cases menstruation is established painlessly, the dysmenorrhea developing several years later and for no apparent reason. Moreover, many women have painless periods alternating at intervals with painful ones. In such cases an organic or developmental fault cannot be adduced as the cause. There is, undoubtedly, a strong psychical element in some cases.

The results of operations for dysmenorrhea leave much to be desired, and in cases where dilatation, curettage, or anterior hysterotomy have failed, the patients can sometimes be subsequently cured or improved by nonoperative treatment.

A number of facts suggest the existence of an obstructive factor in some types of dysmenorrhea. True acquired stenosis of the cervix may follow amputation of the cervix. Anterior hysterotomy relieves the dysmenorrhea in such cases.

The younger the patient when first treated the better the results. Severe cases in patients over twenty five years of age are more difficult to cure, and those in women over thirty are usually intractable and constitute the bulk of the failures.

A moderate degree of arrested development of the pelvic organs is fairly common. There are two very suggestive facts in favor of an endocrine basis in some dysmenorrhea cases: 1, the well known association of dysmenorrhea with sterility; 2, the remarkable success of organotherapy in some cases. Patients who have long and irregular intermenstrual periods and a scanty flow sometimes derive much relief from combined extracts of ductless glands, especially thyroid, ovary, and pituitary.

Of two hundred patients subjected to operation, twenty five per cent. were cured, twenty five per cent. were improved, and fifty per cent. were left unaffected. Dilatation gives the best results in young women with central suprapubic spasmodic pain only, and when divulsion rather than dilatation is performed. Curettage gives the best results in married women, especially when menorrhagia is present or casts are expelled. Hysterotomy proves valuable in acutely anteflexed undersized uteri, especially with a clinical picture of an obstructive causal element.

Of the various forms of drug therapy, the coal tar antispasmodics with atropine, and with the addition of liqor sedans, gave the best results.

The insertion of radium into the uterus, with a consequent cessation of the periods, provides a simpler, safer, and yet equally effective alternative to hysterectomy in women in the thirties suffering from severe and intractable dysmenorrhea. An insertion of 100 to 150 mg. of radium for twenty four hours is usually sufficient. All the disadvantages of an operation are thereby avoided.

Suction Cup Treatment of Chronic Cervicitis.—Wilhelm Fernhoff (*Wiener klinische Wochenscrift,* September 11, 1924) asserts that in obstinate cases of chronic cervicitis, in which other therapeutic measures have failed, the suction treatment often gives good results.

The suction cups are made of glass, gently rolled up at the bottom, with a tube at the top, to which a rubber tube is attached. They are made in various dimensions to fit the different sized cervices. The cervix should fit accurately and the external os should remain visible and not lie against the wall of the cup. A suction syringe of 100 c. c. capacity is then attached and the air is exhausted. The rubber tube is clamped and the patient is left in this condition for five minutes. The os should be frequently examined to see that there is no extensive hemorrhage and that no pain is produced by this procedure. The cup should be applied warm. In due time a mucous plug is seen in the cup, followed occasionally by a little hemorrhage. The vaginal portion of the cervix appears swollen, bluishred, and the external os dilated, and an existing erosion becomes invisible. After removal of the cup the cervix is cleansed, wiped off with tincture of iodine or other antiseptic and a tampon is applied. During the suction procedure the patient may feel a slight drawing or a laborlike pain, which disappears rapidly after the cessation of the treatment.

The treatment is best given three times a week and for the duration of ten minutes. The subjective reaction of the patient needs watching. Previous to each treatment, the internal genital organs should be examined for the presence of any existing inflammatory process.

This form of treatment is especially indicated in cases of chronic cervicitis. It is also applicable to various forms of hypoplasia and atrophy, inveterate parametritis, especially in posterior parametritis, in which the ligaments are greatly relaxed by the resulting congestion. If the first treatment is painful, no further treatments should be given. Even the slightest chronic process in the adnexa is a contraindication. The treatment should not be continued longer than

two months. There may be a retardation or acceleration of the menstrual period, but this is only transient. This treatment may also be given for the emptying of punctured Nabothian cysts.

This form of therapy produces both active and passive congestion, both of which are more intense than with any other form of physical therapy. The congested tissue shows an enhanced power of dealing with infection. In addition mucus is removed from the surface of the cervix, allowing a more effective local medication.

Significance of Backache in Gynecology.—Robert Joachimovits (*Zentralblatt für Gynäkologie,* September 27, 1924) states that gynecological backache is often not due to abnormal female genitals, but to tuberculous or arthritic disease of the posterior portion of the pelvic ring, especially of the sacroiliac joint. Tuberculosis produces small abscesses ventrally, occasionally also dorsally, and sometimes also caries sicca. Arthritis follows trauma, especially trauma from birth; it also occurs in a tuberculous form with disturbances of nutrition and loss of elasticity in the cartilage and relaxation of the sacroiliac ligaments. Of the tuberculous and arthritic symptoms, only the pain on crossing the legs and tenderness of the synchondrosis on vaginal and rectal examination stand in the foreground. These conditions, that are demonstrable roentgenologically with great difficulty, were not associated with either mobile or fixed retroversion flexion.

Radial Pulse Volume and Radial Pulse Work During Labor.—Walther Haupt (*Zentralblatt für Gynäkologie,* October 25, 1924) shows that the radial pulse volume is distinctly diminished during labor pains in more than two thirds of the cases, and in some cases some of the individual pulse beats almost disappear. In the remaining cases there is an alternating rise and fall, and in only one case was the rise constant. Consequently, the pulse volume a minute is frequently not increased in spite of the increase in frequency of the beat, but it remains constant or even considerably diminished. The individual and minute work values behave similarly; nevertheless, the loss in size is relatively slight in both values, and occurs more rarely in the latter.

The effective factors in the rise of the pulse volume are the following: expression of the uterus, increased abdominal pressure, diminished thoracic pressure, muscular work, diminished resistance in the arterial field, and nervous influences; the reverse occurs with diminution of the abdominal pressure, increased thoracic pressure, increased peripheral resistance, and nervous influences; technical errors must also be taken into consideration. A particularly marked effect upon the diminution of the volume was noted from groaning and straining, which may be explained by the predominance of the thoracic pressure over the abdominal pressure.

Treatment of Pernicious Vomiting in Pregnancy by Gastric Lavage and Carbohydrate Rectal Feeding.—Stanley E. Denyer (*British Medical Journal,* September 13, 1924) summarizes the essentials of treatment in cases of pernicious vomiting in pregnancy as follows:

1. Rest in bed. 2. Gastric lavage, with solution of sodium bicarbonate one dram to the pint, one or two pints being used. 3. Solution of adrenalin, five minims hypodermically every three hours for a few doses until vomiting ceases, or the adrenalin solution may be given by the mouth in doses of ten or twenty minims in a little water. It will be found that this drug is efficient in stopping many kinds of vomiting. 4. The omission of all feeding by mouth, at first, and feeding by rectal salines containing from half an ounce upwards of glucose to the pint, with a small quantity of sodium bicarbonate added if there is any diacetic acid in the urine. 5. The addition to the evening salines of thirty grains of potassium bromide to induce sleep and reduce irritability of the nervous system. 6. The gradual increase in feeding by the mouth, beginning with small feeds of water.

In cases seen with progressively increasing severity of the vomiting, the oral administration of 1 in 1000 adrenalin solution in doses of ten minims in two drams of water at three to six hourly intervals will in many cases be sufficient to stop the vomiting. The diet at the same time should be light and given at short intervals. The treatment by lavage, outlined above, and rectal salines should be reserved for the more serious cases, or to those which do not respond to treatment by adrenalin.

Intrauterine Radium Treatment of Benign Gynecological Hemorrhages.—Gustav Halter (*Zentralblatt für Gynäkologie,* September 13, 1924) says he has achieved some good results with the intrauterine (not intravaginal) application of radium in eighty-nine cases of hemorrhage. He was able to produce amenorrhea sixty-four times and a diminution of the bleeding fifteen times. Vaginal applications are made only for carcinomata. Unfortunate accidents, such as the formation of hematometra, exudates, and pyosalpinx can be avoided by the observance of strict indications, namely, the palpatory and anamnesic absence of inflammations in the region of the genital system, and a most carefully maintained asepsis. Hematometra may be avoided by pushing the tube of radium up to the fundus; in this way agglutinations in the lower portion of the uterus and, especially, in the cervix can also be avoided.

In the hemorrhages of young persons, which have persisted in spite of all other methods of treatment, a weak intrauterine application of radium (but not over eight hundred milligram hours) can be made. If this produces no result the use of radium should not be repeated. In the preclimacteric and climacteric hemorrhages a dose smaller than that recommended by most authors (nine hundred milligram hours) is advised as slight menstruation seems to be more desirable than permanent amenorrhea. The possibility of injury to the ovum in a subsequent pregnancy in case that a permanent amenorrhea is not achieved must be borne in mind, but this danger is no greater than with röntgen rays. At any rate the treatment with radium should be used with great reserve in young women and in those of the childbearing age.

High Occipital Presentation in Eclampsia.—Rudolf Fischel (*Zentralblatt für Gynäkologie,* August 30, 1924) asserts that subcutaneous symphysiotomy is the operation of choice in medium grades of contracted pelvis in multiparæ, whenever there is protracted labor with a premature escape of the amnion and when it is certain or at least probable that the interior of the uterus is infected. This operation is preferable to Caesarean section and perforation. The same rule holds also in aseptic cases in multiparæ, where there is a contracted pelvis of medium grade. In primiparæ, under the conditions mentioned above, a suprapubic Cæsarean section is done. In infected primiparæ a perforation is done even on the living child.

Symphysiotomy is contraindicated in markedly contracted pelvis, as otherwise an injury of the joints and ligaments would occur; in irregularly contracted pelvis, as it is impossible to calculate the amount of space that would be gained by the separation of the bones, and in primiparæ, because of rigidity of the soft parts.

Suggestions in the Treatment of Puerperal Sepsis.—J. R. Campbell Canney (*British Medical Journal,* August 30, 1924) advances the following suggestions: When fever appears in the puerperium, having excluded maladies outside the pelvis which may cause it, it is safer to give an anesthetic and carefully examine the patient's pelvis than to "wait and see." If intrauterine sepsis is present, explore the uterus and take steps to empty it or clean it, or both. To wait and see if the fever will subside may mean waste of precious time. A socalled sapremia is quite often the precursor of the most virulent septicemia, and anyhow a sapremia will not be improved by leaving even small and removable fragments of placenta or membrane *in situ,* if they are poisoning the patient. The septic uterus will not involute, but the modified Carrel-Dakin treatment, assisted perhaps by drugs, will help involution better than anything at our disposal. If antistreptococcal serum is to be used, use it frequently until the temperature falls. Further adjuncts are "peptone shock" and intravenous eusol. Take a culture from the endometrium and from the blood, as a vaccine later may be of value, especially if prepared from the blood. Pay careful attention to posture in the nursing of these patients. Fowler's position will aid drainage, whereas the supine position will tend to dam back secretions. Similarly micturition and defecation in a complete sitting position are useful aids. In early infection of the adnexa, the modified Carrel-Dakin method may possibly precent the necessity of abdominal section, and will certainly speed up recovery. Where anemia or debility is caused by hemorrhage or toxemia keep a special lookout for sepsis. Perform all manipulations or instrumentation with extreme gentleness whenever possible, and practice asepsis most punctiliously. Sew up all tears of soft parts immediately.

PRIVILEGED COMMUNICATIONS—NURSES AND ARMY SERGEANTS

The Nebraska Supreme Court holds, Culver v. Union Pacific R. R. Co., 199 N. W., 794, that a professional nurse assisting a physician to whom confidential communications have been made by a patient is an agent of the physician. She stands in the same relation of confidence to the patient and may not be permitted to testify to such communications unless the privilege has been waived by the patient.

A sergeant of the United States Army Medical Corps, who is not a physician, who acts under the regulations of the army in furnishing to soldiers medical or prophylactic treatment for venereal diseases, and who does not fall within the rule as to assisting nurses above stated, may, the Nebraska court holds, testify to the fact that application was made to him for such treatment, and as to the nature of the service rendered by him, where such facts are material to throw some light on the question at issue.

NEGLIGENCE DURING AND AFTER ETHERIZATION NOT PROVED.

Actions were brought against a physician and a dentist for damages for personal injuries alleged to have been caused by their negligence. The Massachusetts Supreme Judicial Court, Cross v. Albee, 145 N. E. 45, said that it was the duty of the defendants in the practice of their respective professions to possess a reasonable degree of learning and skill and to exercise ordinary care and diligence. As stated by the court in its opinion, affirming a judgment on a directed verdict for the defendants, the physician was specially called to administer ether to the plaintiff, whose uncontradicted statement was that she was then in perfect health. The plaintiff fully understood he was not employed as a general practitioner to prescribe for her ailment and become her attendant physician, or to provide necessary nursing because of her alleged enfeebled stated caused by and following the extraction. No evidence was offered on which the jury would be warranted in finding that etherizing a patient to produce insensibility to pain arising from the extraction of teeth "is a serious and dangerous operation," or that "to make the treatment reasonably safe and successful required a careful diagnosis and chart of the patient's previous health, constitution and susceptibility, and a reasonable preparation and regulation of the same before the ether application." The plaintiff called the defendants as witnesses. If they were believed by the jury, the court held, no lack by the physician of the use of adequate medical knowledge or of professional skill was shown. If they were disbelieved the remaining evidence was held insufficient to warrant a finding of causal connection between any negligent act of the defendant and the physical ills from which the plaintiff contended she suffered after the operation.

There was no evidence to show that, as alleged, a proper pack was not used to prevent blood from going down the patient's throat during the operation, the burden of proving which rested on the plaintiff.

SCOPE OF HYPOTHETICAL QUESTIONS

It is not allowable in asking a hypothetical question to incorporate into it the opinion of another expert. What facts a hypothetical question must cover are to be determined by the sound discretion of the trial judge.—Laughlin v. Christensen, 1 Fed. (2nd) 215.

PERMITS TO PRESCRIBE ALCOHOL

The Missouri Court of Appeals holds, State v. Sass, 266 S. W. 765, that Rev. St. 1919, §6592, providing that permits to physicians to prescribe ethyl alcohol and wine "may" be granted by the judges of the county court does not make it the absolute duty of the county court to issue a permit.

TUBERCULOSIS HOSPITAL DISTRICTS SEPARATE ENTITIES UNDER MASSACHUSETTS STATUTE

In a proceeding under the Massachusetts Workman's Compensation Act for injury to a laborer in a tuberculosis hospital established under Mass. St. 1916, c. 286 (G. L. c. III, §§78-91), the Massachusetts Supreme Judicial Court holds, Peck's Case, 145 N. E. 532, that such hospitals are managed by county commissioners as trustees, the funds for their maintenance ultimately coming from a district served within the county, which districts are separate entities, and the applicant was not an employee of the county so as to make it liable under the Compensation Act, but was an employee of the county commissioners acting as trustees for the tuberculosis hospital district.

TRIAL COURT HELD NOT IN ERROR IN REFUSING TO ORDER X RAY EXAMINATION OF PLAINTIFF WITHOUT HIS CONSENT

The defendant in an action for personal injuries asked the court to appoint a disinterested physician at the defendant's expense to make a physical and x ray examination of plaintiff. The court ordered the physical examination, but declined to make an order requiring the plaintiff to submit to an x ray examination without his consent upon the ground that there was always a possibility of injury in connection with the taking of x ray plates. The plaintiff refused to give his consent to an x ray examination unless he should be given a bond indemnifying him against injuries that might possibly result to him from the taking of the pictures. It was held, Lawrence v. Pickwick Stages (Cal. App.), 229 Pac., 885, that since the defendant contended that such an examination was important to its case, and since the plaintiff was willing to submit to it upon being indemnified against injury, there was no good reason why the defendant should not have so indemnified him. The court said: "The evidence was required by the defendant; if it involved any cost in money to secure it, that was a proper charge against defendant, and if it involved any cost in physical injury to plaintiff, that was, equally, a matter for which the defendant should pay." It was, therefore, held that the trial court did not err in not ordering an x ray examination of the plaintiff.

WHETHER CONDITION FOLLOWING INJURY WAS RESULT OF CARELESSNESS IN SELECTING PHYSICIAN AND SURGEON QUESTION FOR JURY

In a personal injury action the Supreme Court of California held, Dewhirt v. Leopold, 229 Pac., 30, that where the question of whether or not infection and necrosis which followed the injury were the result of carelessness or negligence chargeable against the plaintiff in making his selection of physician and surgeon were submitted to the jury upon full and fair instructions, the Appellate Court was not at liberty to disturb the jury's implied findings that there was no carelessness in making such selection, inasmuch as there was ample evidence to support them. There was nothing in the record to show that plaintiff was negligent in the selection of a physician and surgeon and no substantial testimony by which it could have been inferred that the infection and necrotic condition were attributable to inattention or maltreatment on the part of the attending physician and surgeon. No physician or person skilled in medicine or surgery so testified.

Psychological Factors in Hyperthyroidism*

NOLAN D. C. LEWIS, M.D.
Washington, D. C.

The basic pathogenesis of hyperthyroidism is as yet unknown, therefore we may consider it to be a relatively safe procedure to offer a few suggestions tending to shed additional light upon this disease syndrome, which is in many respects one of the most complex in all physiobiology in spite of the fact that it has manifested itself as few other diseases have, into more or less distinct or well recognized chemical, physical and psychological panels or aspects, all of which are integrated into the total organism; a general subject which has been discussed elsewhere (1).

In order to reinforce the foregoing statements let us turn to some of the research and thought trends expressed in the literature on the subject. Crile (2) began a recent discussion of the problems of hyperthyroidism with the following admission: "At the outset let us admit that we know of no specific pathological basis for the syndrome that we designate as hyperthyroidism. We have not sufficient information regarding the mechanism of the disease to argue regarding its pathology. We admit that there is no specific criterion whereby to establish the diagnosis in the borderline cases, that is, to determine at what stage altered function on the outer boundaries of normality ends and hyperthyroidism begins." He emphasizes surgery as being the shortest road to recovery in all types of goitres including the simple forms (if pressure exists), adenomatous varieties, malignant glands, and the exophthalmic forms. He remarks on the low mortality in hundreds of cases of exophthalmic goitre operated in by various technical procedures, but comments little upon the percentage of cures or good results. Again we may quote from a digest of Boothby's (3) impression: "Exophthalmic goitre is a constitutional disease apparently due to excessive probably abnormal secretion of an enlarged thyroid gland with pathologically diffuse parenchymatous hypertrophy and hyperplasia. The condition is characterized by an increased basal metabolic rate and the resulting secondary manifestations, by a peculiar nervous syndrome and usually by exophthalmos, with a tendency to gastrointestinal crises of vomiting and diarrhea. The cause of the altered pathology and disturbed function of the thyroid gland is not known. In reply to the question 'If both exophthalmic goitre and adenomatous goitre with hyperthyroidism are due to an excess of thyroid secretion, can there be a differentiation into two diseases?' several hypothetical answers are possible, but the one held by Plummer as the most probable is briefly as follows: The symptoms of adenomatous goitre with hyperthyroidism can be produced by the administration of an excess of thyroid extract or thyroxin, therefore adenomatous goitre with hyperthyroidism is regarded as due to the presence in the body of an excess of normal thyroid secretion. The symptoms of exophthalmic goitre, however, cannot in their entirety be produced by thyroid feeding. The symptoms which are not produced in characteristic form are exophthalmos, the typical gastrointestinal crisis, the peculiar nervous phenomena and finally the metabolic status, as the result of which a postoperative reaction may arise which terminates in death within about thirty-six hours.

All of these symptoms which are characteristic of exophthalmic goitre can probably be explained on the assumption that the secretion of the thyroid gland is not only present in excess but is also an abnormal product."

Holst's study (4) of three hundred cases of exophthalmic goitre took him into the fields of internal medicine, surgery, pathology, ophthalmology, gynecology, neurology, psychiatry and also into biochemistry. He concluded that the actual cause of the tissue change was still unsolved although the thyrosis and the exophthalmic adenomas had been thoroughly studied. He also emphasized that primary exophthalmic goitre does not occur endemically while the secondary form is endemic in most cases. Among many others Weiss (5) has emphasized the psychoneurotic and nervous disturbances in hyperthyroidism, and in his opinion, which is also similar to some others, these psychic disorders in patients with toxic goitres are not caused by the toxemia, but are parallel symptoms of a degenerative constitution, each group of symptoms being able to influence the other. Oswald (6) also believes that exophthalmic goitre occurs only in subjects with a neuropathic disposition. He induced hyperthyroidism artificially in fox terriers, but only in those said to be degenerated by inbreeding. He concluded that the thyroid secretion lowered the general threshold of visceral nervous system response.

*Read before the Washington Society for Nervous and Mental Diseases, on December 18, 1924, and at the January, 1925, session of the Medical Society of the District of Columbia.

Copyright, 1925, by A. R. Elliott Publishing Company.

Kessel (7) and his coworkers also state that the basic pathogenesis is entirely uncertain, and remark that "the administration of the thyroid gland may augment the symptoms of exophthalmic goitre or evoke some of them in normal individuals, but it has never been possible to produce artifically a typical clinical picture of exophthalmic goitre. The only constant symptoms that Carlson (8) was able to produce from feeding large quantities of thyroid extract to man and other vertebrates were loss of weight, gastroenteritis, and diarrhea. He never succeeded in constantly producing exophthalmos, tachycardia, goitre or nervousness." Other substances, notably cocaine, epinephrin, ergotoxin and tyranin, also augment or reproduce the symptoms even more accurately."

Fox (9) has considered over five thousand autopsies on captive wild animals, and has had as well a large clinical experience with diseases of animals at the Philadelphia Zoological Gardens. Upon many occasions he has seen animals with evident goitres, some of which produced pressure symptoms, but he has not been able to detect bulging of the eyes or especial nervousness. In making a diagnosis he used care to exclude mild swelling of the gland seen in acute infectious disease, and under conditions of sexual activity. In short "no case of exophthalmic goitre as the symptom complex is known in man has been observed, yet the anatomical alterations, hyperplasia without colloid and with papillary or solid adenomatoid character, are abundantly represented. For the pathologist to accept a case as toxic goitre, I would ask evidence of enlargement of the heart and perhaps in addition degeneration of the myocardium." Two cases, one in a raccoonlike dog and the other in a grey wolf, presented syndromes resembling somewhat that of man, but there was no exophthalmos or nervousness during life.

Attempts have been made to throw light on the subject through physical chemical investigation, and Starlinger (10) has usually found in cases of struma that the arterial plasma has a coarser dispersion than the venous plasma, although in some cases an inverse relationship is found. The former is present with a hyperfunctional gland while the latter exists with a hypofunctional one. The function of the thyroid gland is here interpreted as a mechanism for demolition of high molecular protein compounds. This is a suggestion from the physiochemical aspect of the problem which when further developed may aid us in diagnosing borderline cases.

Let us now discuss some of the obvious relationships between the thyroid gland, its disorders, the genital organs, erotic mechanisms and emotional states. Crotti's well known classification of hyperthyroid states is based upon the periods of development of the genital system. Thus: 1. Infantile group (children up to ten years of age—the genital system is in its expectancy). 2. Juvenile group (from ten to fifteen years of age—genital system is undergoing development). 3. Adolescent (fifteen to twenty-five years—genital system has reached its maturity). 4. Adult (after twenty-five years of age).

Gaskell (11, 12) first pointed out a similarity between the uterine glands of Scorpio and the thyroid gland of the lowest vertebrate, Ammocetes (13). Brown (14) gives an excellent summary of the phylogenetic relationship as follows: "It will be found that the position and arrangement of the uterus in Limulus closely resembles that of the thyroid with its thyroglossal duct in Ammocetes, the larval lamprey, one of the most primitive of the vertebrates, not only is the presence of this duct thus explained but as Gaskell says, 'The relationship which has been shown from time immemorial to exist between the sexual organs and the thyroid in man and other animals, and has hitherto been a mystery without any explanation may possibly be the last reminiscence of a time when the thyroid glands were the uterine glands of the paleostracan ancestor.'"

These connections may with interest be traced back to the still earlier development of the segmental coxal glands, of which the pituitary, thyroid, tonsils, thymus and others are representative paired survivals. After noting the close phylogenetic relations between the tonsils and thyroid gland it is easier to understand the connection between tonsillar sepsis and a variety of thyroid enlargement. Perhaps from this angle there are two kinds of goitre, one with an emotional pathogenesis and the other bacterial in origin.

Chief among the numerous trophic and other changes in hyperthyroidism Blondel (15) has found atrophy of the uterus. This atrophy is possibly the explanation of sterility in certain cases. He also noted how much more prevalent hyperthyroidism was in women during the war than other years and explained it by the prevalence of emotional factors.

Ewing (16) notes that the occurrence of thyroid tissue in ovarian tumors has long been recognized. They are relatively frequent in ovarian teratomas while very rare in testicular ones. Clinical evidence has been brought to show that these ovarian thyroid tumors may function vicariously for the thyroid gland, since they may exist as small islands of thyroid tissue or become bulky tumors. In fact Kovacks (17) has recently described one of these rare tumors of the ovary which gave goitrelike symptoms. In short symptoms of exophthalmic goitre developed with the tumor and subsided after its surgical removal. The structure of this tumor was that of a colloid goitre and appeared to be morphologically, chemically and functionally true thyroid tissue. One wonders whether these tumors are all teratoid rests or are produced by downgrowth of superficial ovarian epithelium, a metamorphosis as was clearly shown by Bauer to occur in some cases, but probably not all originate according to Bauer's idea.

We may now consider some of the current ideas regarding the rôle of emotional factors in hyperthyroidism. Maranon (18), one of the pioneer investigators in this realm admits that emotional stress is particularly likely to induce hyperthyroidism when there is already a predisposition to excessive thyroid function, but he insists that emotional stress alone may be sufficient to bring on hyperthyroidism even in the normal. He classifies hyperthyroid states into seven different types in addition to and separated from the classical exophthalmic goitre. These types are labeled 1, cardiovascular form; 2, nervous form; 3, consumptive form; 4, digestive form; 5, diabetic form; 6, climacteric form, and finally, 7, the simple form which may later develop into the exophthalmic

type. None of the symptoms are distinctly pathognomonic and in dubious cases he always rejects the assumption of hyperthyroidism unless there are present at least three of the principal symptoms including unstable tachycardia, tremor, enlargement of the thyroid, exophthalmos, retraction of upper eyelid, patient losing weight, pronounced motor restlessness, emotional instability, and sensations of heat with vasomotor irritability localized especially in the thyroid region.

Juarros (19) has drawn attention to combinations of hyperthyroidism and neurotic symptoms often spoken of erroneously as hysteria. Many of these patients are old maids, selfcentred, melancholy and irritable with complaints of fatigue, and with insomnia. I have two cases now under treatment with symptoms exactly corresponding to this variety of reaction described by Juarros. From another angle Snowden (20) of London has stated that hyperthyroidism and subsequent hypothyroidism which results are not readily distinguished in the two cases where they arise from, 1, an anxiety state in which bacterial toxemia is not a particular strong feature, or 2, from bacterial toxemia in which the anxiety state is not noticeably established. "When the cause which has originated this anxiety state has been removed the condition then may need the endocrinologist or bacteriologist." Any attempts to treat these cases without psychotherapeutic measures will too frequently end in disappointment.

True hyperthyroidism rarely occurs in children before puberty. In Sattler's (21) group of 3,477 hyperthyroid patients, only 184 were under fifteen years of age. I have not had the opportunity as yet to study his report carefully, therefore I am unaware of the percentage of females represented. Buford (22) in 1922 was able to find only eighteen cases of hyperthyroidism in children under twelve years of age in twenty years of literature. Eight of these cases were in children under five years, the youngest being that reported by Klaus (1914) an infant nine months old (23). However, Clifford White (1912) has reported a case of congenital exophthalmic goitre. Buford's patient was only six years old, being the youngest reported to be operated on where operation produced relief. This author's case and three others he mentions were in females, in fact no other sex is mentioned in his comments on the literature. Frantz (24) has reported the very interesting case of a female child who had typical hyperthyroidism at the age of one and one half years. This child was nine years of age at the time she was examined by the author, but tested to the mental age of 12.2 years. In addition she had a marked neurosis with peculiar behavior. Her mother also had exophthalmic goitre. He considers it to be a neurosis of the entire vegetative nervous system.

Brooks (25) has discussed the situation of temporary or physiological hyperthyroidism in young people of both sexes brought about by abnormally great demands upon the thyroid, and the result of developmental growth associated with too much emotional output. He describes several instances and minimizes the need for surgical or medical interference but emphasizes social and mental management and readjustment. He says that "Freudian impulses" have very little, if anything, to do with these mechanisms, a statement characteristic of those who have no insight into the breadth of analytical psychology; however, he immediately proceeds to say that the syndrome occurs in temperamental persons whose unbalanced habits of life cause strain upon the thyroid and other glands.

The physiological relations of the size of the neck to the sexual life was well recognized in the ancients and Lusk (26), quoting from Garrison's *History of Medicine,* states: "The Romans recorded the girth of the neck of a young woman with a thread or tightly fitting necklace and sought to determine defloration or pregnancy from the increase in the size of the neck, although they had no knowledge that this was due to an increase in the size of the thyroid gland."

In 1923 I (27) published an account of the hyperthyroid question as it then appeared, together with notes on the analysis of the mental factors playing a rôle in two cases, one of which had been thyroidectomized without result. Both patients exhibited several features in common. The infantile father attachment persisted with a powerful unconscious urge toward the father imago, both were profoundly influenced by autooerotic cravings, and definite hyperthyroidism did not present itself until very acute conflicts began between instinctive desires and moral codes. After observing the results obtained at that time by psychotherapy I was convinced that surgical procedure when successful is instrumental in removing a few symptoms from the syndrome, thus breaking the arc, but it frequently fails, for surgery is powerless to remove the underlying predisposing factor and its by products in the personality.

The foregoing survey of some present trends of thought concerning hyperthyroidism may now be summarized into a few points which seem to be quite definitely settled, and which have a direct bearing on, or prepare the setting for the considerations about to follow:

1. There is no generally accepted theory of pathogenesis of exophthalmic goitre.
2. The impression has arisen universally that it is a many sided disease, not dependent entirely upon an excess of thyroid secretion.
3. That exophthalmic goitre does not appear spontaneously in infrahuman forms, nor has it been completely induced by experimental procedures.
4. That phylogenetically the thyroid once functioned as a uterus in primitive forms.
5. Definite thyroid rests or ovarian metamorphoses into thyroid tissue occur as neoplastic conditions.
6. That uterine atrophy with sterility is prone to occur in hyperthyroid states.
7. That the disease is rare in children before the onset of the pubescent state of the genital organs, and shows a preference for females of all preclimacteric ages, rarely developing after the climacteric.
8. And finally that emotional factors are obvious, playing an important rôle in the production of the symptoms and that perhaps unconscious motives serve to determine some of the pathognomonic features. Therefore it may be said with conviction that true hyperthyroidism is a product of or at least closely associated with emotional and sexual developmental disorders, and probably represents a particular constitutional make up in the broadest sense of the term.

I shall now present a few impressions from the viewpoint of analytical psychology on cases of exophthalmic goitre to emphasize what I believe to be the correct method of approaching the analysis of the disorder.

1. Chemical investigations are of utmost importance in ascertaining the state of the autonomic nervous system, the basal metabolic rate and the carbohydrate tolerance. It goes without saying that these tests should be satisfactorily done in each case.

2. The physiological level must be carefully and systematically investigated at length with particular attention to:

a. Gastrointestinal disturbances.

b. Cardiac irregularities.

c. The presence of exophthalmos. (Here it is well to keep in mind the great variability in exophthalmic goitre cases, concerning this symptom which may not be appreciably present or may progress to a complete blindness such as occurred in a patient reported by Lahey (28). In spite of the removal of the superior cervical sympathetic ganglia, it was finally necessary to enucleate both eyes).

d. Additional eye signs including widening of palpebral fissures and condition of pupils.

e. Presence of tremors and toxic crackling in the extremities.

f. Activities of sudoriferous glands—temperature and state of peripheral circulation, particularly of the extremities.

g. The size of and manifestations of tension in the thyroid gland.

h. Condition of reflexes.

i. Presence or absence of Lian's sign. Maranon (29) reported on this sign which was found present in eighty-five per cent. of cases with hyperthyroidism. A very gentle rubbing of the neck provokes a reddening of the skin in many neurotic subjects. In cases of hyperthyroidism this redness is limited or localizes quickly just above the thyroid gland. Maranon discusses the relation of this sign (which he described in 1919) to Lian's local hyperesthesia in hyperthyroidism. I have noted in several cases that such a bright red spot with margins quite sharply limited appeared over the thyroid area during the discussion of unpleasant emotional material. In fact in certain cases it could be depended upon as indicating the presence of unpleasant associations (complex indicator).

3. The following mental traits and behavior peculiarities have been found present in the exophthalmic goitre situation. From the viewpoint of psychological analysis the material is unusually rich in content.

a. Intense emotional swings throughout life, periodical and brief in nature, but with definite depressions and agitations.

b. Love life inconstant with frequent dissatisfactions with love object.

c. Unexplainable fears concerning places and people.

d. Unexplained but active and intense hatreds for certain people and animals.

e. Erratic behavior in solemn or formal situations.

f. Frequent and often serious misunderstandings with members of the family.

g. Frightening dreams which are frequently incestuous in nature.

h. A number of patients have nocturnal anxiety attacks, with pseudoasthmatic, pseudoanginal and tachycardial symptoms accompanied by numbness and great fear.

i. Analysis discloses that as children in the pregoitrous stage these patients are extremely sensitive and selfconscious with exaggerated feelings of inferiority, which are too often discovered and utilized as sadistic outlets by their playmates. Especially painful are the memories of any disparaging comments made even in fun, concerning their physiognomy.

j. Infantile birth phantasies persist with much power in the unconscious.

k. Early sexual traumata have been found to play an important rôle in the pathogenesis of the disorder.

Ten cases of frank exophthalmic goitre as well as numerous psychotic patients with goitre have been psychoanalyzed with results which have led us to believe that the disease is a severe, often structuralized neurosis depending upon an early powerful bond of father attachment dominated by an unconscious incest mechanism, and with strong autoerotic cravings.

With the exception of the psychotic cases, these patients have been largely reconstructed chemically, physically and psychologically. In some the results are better than could have been expected from surgery, and the detailed accounts of the psychotherapeutic hours will be published later, therefore it must suffice for the present to confine our remarks to the nature of the mechanism.

Since true exophthalmic goitre is less frequently seen in men than in women it may be well to outline briefly the situation in the only male patient with goitre I have as yet had the opportunity to investigate. His case deserves detailed consideration in another publication.

Case.—A man, twenty-three years old, a member of a homosexual compact, came to be treated for nervousness, anxiety and constant headache—he had been in this condition for at least seven years. Two years before consulting me he had had a bilateral thyroidectomy performed by a well known competent surgeon, after which some of his symptoms became attenuated. He still had some tremor, slight exophthalmos, a moderate tachycardia and a basal metabolism 20 plus. This man had passed through terrific conflicts and had undergone severe persecutions because of his homosexual constitution, which was by no means entirely acceptable to his conscious life.

The analysis of the early home situation in which he strongly identified himself with his beautiful mother (he was vain and narcissistic), his prolonged masturbatory activity and phantasies, and particularly his persistent curiosity towards his father's genitals with subsequent longing to take the mother's place in his father's affection, all of which later turned to hatred of the whole situation—rendered him psychologically into a woman with impregnation phantasies toward the father: Thus he may be considered categorically as a female. In this case the analysis revealed the powerful mother fixation with mother identification, overt autoerotic trends, and overt homosexuality with an inverted incest craving. His symptoms were removed by psychotherapy and he has been able to sublimate his homosexuality in

creative work. These psychotherapeutic experiences with goitre together with a consideration of the principles of phylogenetic and ontogenetic fundamentals of development have led to the following formulations which are the basic points in my thesis on pathogenesis.

1. Fear states—anxiety—*angst*—are universal emotions present in all living animals. It is a self-protective mechanism—a phylogenetic flight lying deeply in the remote phyelytic past.

2. All symptoms of hyperthyroidism, chemical, physiological and psychological, are exact duplicates of those of fear.

3. Exophthalmic goitre is a special type of hyperthyroidism—it is what one might call structuralized fear—the constant flow of the river of emotion has cut its channels definitely in the structure and functions of the tissue. Even the eye signs in exophthalmic goitre are those of fear. Collins (30) states that enlargement of the pupils, increased prominence of the eyeballs and widening of the palpebral fissure increase the range of circumferential vision, thereby assisting the animal in perceiving the early approach of danger, and in obtaining safety in flight. Mydriasis brought about by emotional influences acting through sympathetic nerves on dilator fibres of the iris may explain the psychic influences on production of glaucoma.

4. Exophthalmic goitre results from a specific psychological situation. Other forms of hyperthyroidism and goitre may not and probably do not arise in this way.

5. There is a universality of normal father attachment or fixation with transitory and finally converted or sublimated father incest cravings—naturally more marked and persistent in girls. In certain individuals an overdetermination or heavy bond fixation on the father with incest cravings stronger than normal, but usually unconscious, and failure in sublimatingt these, expresses itself through the thyroid segment, because it is phylogenetically a uterus, and thus at maturity readily lends itself to symbolic expression.

6. Thus the tumescence of the thyroid may represent a father impregnation phantasy (an impregnation phantasy materialized in the thyroid) the substance of which is composed of hyperplastic tissue producing an excess of secretion initiating and perpetrating bodily changes which become the classical, physiological and chemical part of the picture.

7. Thus exophthalmic goitre is an aggravated form of anxiety neurosis, a structuralized fear at the symbolic level, caused by a particular pathogenic situation in the form of repression of father impregnation phantasies plus autoeroticism and active sexual suppressions—a mechanism expressing itself in the thyrotrophic individual through the thyroid segment because of its phylogenetic history and relations which accounts for the fact that fifteen females to one male are affected by this disease syndrome, and I personally believe that the male cases are instances of early psychogenetic inversion or distortion involving the same mechanism.

8. This paper is not intended to depreciate any particular method of treatment, and I am well aware that exophthalmic goitre is apparently cured or markedly improved by a variety of procedures, including surgery, x rays and drugs, since these methods remove or suppress the offending organ, thus alleviating distressing symptoms, but I do not feel that the basic neurosis is thus removed, a feature which must be taken into consideration if the therapeutic attack is to be entirely successful. Granting that patients are completely cured by surgery or other mechanical means, the results could not serve as potent arguments against a psychogenic origin, since the emotional expressions of an individual may be permanently altered by the excision of an affective organ, for example the testicles, for in both instances the means of that particular expression has been obliterated.

Carcinoma of the Sigmoid Colon Rupturing Into the Abdominal Wall*

WILLIAM C. MENNINGER, M.D.
Topeka, Kan.
and HALL G. HOLDER, M.D.
San Diego, Cal.

There are two points worthy of attention in this case: first, practically the entire absence of symptoms pointing to the presence of a far advanced adenocarcinoma of the bowel with extensive metastasis, and second, the rupture of an annular carcinoma of the gut into the abdominal wall, without peritonitis.

Case.—The patient was an adult white woman, aged sixty-seven, divorced, born in Ireland. Her chief complaint was of pain and swelling in the left groin of three weeks' duration. Her mother died at eighty-six from "heart trouble, cirrhosis of the liver, and softening of the brain," and her father died at eighty-six from a "stroke." One brother and one sister were living and well, one brother died at seventy-five from a "stroke." There was no history of miscarriages, tuberculosis, malignancy or familial disease in the immediate family.

Her general health had been good until the present illness. She had had no childhood affections of serious moment, but had an attack of erysipelas twenty-four years ago. She had no headaches, eyes were hyperopic, ears and nose objectively and subjectively negative. For three weeks she had had a discharge from the throat, and her "tongue felt big and would not protrude"; there was no sore throat or abscessed teeth, the upper teeth had been extracted several years ago. Respiratory organs were negative for pneumonia, pleurisy, hemoptysis, and cough; she had night sweats lasting over a week one month ago. She had had some dyspnea for the last four or five months; cardiac symptoms were otherwise negative.

Gastrointestinal symptoms: Her appetite had been good, she was generally not constipated and there was no abdominal pain at any time. Six months ago, during a socalled nervous breakdown, the patient had loose bowel movements, which gradually became less frequent. At present, she has three or four movements a day; no history of melena.

Genitourinary symptoms: Negative for diuresis, dysuria, hematuria. Nocturia three or four times, which had been increasing for the last few years; voided seven or eight times during the day. Menstruation began at fourteen, was regular, lasted three days, no pain. The menopause occurred at fifty-four; no leucorrhea since menopause. She was first pregnant at twenty-two; the child is living and well; she had one miscarriage at twenty-four, and no other pregnancies. She denied venereal disease. She was married at twenty and lived with her husband only three years. At the age of forty-nine, she had a pelvic operation, which, from the patient's description, was probably a correction of the position of the uterus. It recurred four years ago, and a pessary was inserted then which was never removed until six months before admission to hospital on account of the present illness.

The onset of the present illness occurred about six months ago, when the patient became somewhat irritable and complained of discomfort in the lower abdomen. Her physician told her she had a "nervous breakdown," with a "weak heart and lumbago." He removed the vaginal pessary which had been in place for over three years without removal, and told the patient's daughter that a "tumor" might result from wearing the pessary so long. The patient began to lose weight about this time, although she believed her weight had been somewhat declining for the last two years. After a time, she returned to her work as a housekeeper, until six weeks ago when she was again troubled with "lumbago," and stopped work. Three weeks ago, she first noticed a pain in the left groin which within a few days prevented her from standing, and she noted a swelling at the site which progressively enlarged. She had been bedridden about two weeks before admission. Her appetite was unimpaired; her weight loss not impressive; bowel movements about four times a day; urinated seven times if out of bed. She generally felt very well; there was no history of previous swelling in this region.

Physical examination showed a tumor mass, about fifteen by eighteen cm., obliterating the inguinal fold, extending from the crest of the ileum laterally to the symphysis medially, and from a distance of about ten cm. above the inguinal ligament to about three cm. below it. The tumor was tense, fluctuated, was exquisitely sensitive and tender, and superficially reddened with dilated vessels. Fixation could not be determined because of the size of the mass and the pain, but the mass seemed distinctly extraperitoneal. The patient's hip could not be moved without pain. Lymph nodes elsewhere were not enlarged. The abdomen was large and full, but the patient stated that it had always been so.

The patient was an elderly white woman, anemic, nutrition only fair. She was in no apparent distress when quiet; not acutely ill. The eyes showed contracted pupils, but reacted to light and distance; extraocular motions were normal. Nose and ears were objectively normal. The tongue was thick, dry, protruded with difficulty, and was heavily coated. Teeth, uppers extracted, lowers poorly kept, with snags and caries. Throat was injected, with thick creamy exudate on the surfaces. Chest was normal in shape and contour; left nipple inverted, otherwise breast was normal. The heart was somewhat enlarged, pulses were palpable, a palpable thrill which was visible over the central portion of the precordium; questionable mitral murmur; second aortic and second pulmonic equal; suggestion of aortic roughening. Lungs were hyperresonant, with

*From the Second Surgical (Cornell) Division, Bellevue Hospital.

somewhat exaggerated breath and voice sounds; no râles.

The abdomen showed a very thick panniculus; no organs were palpable; no masses or rigidity; tenderness absent except in region of tumor. Genitals were normal externally; uterus seemed to be in normal position but fixed; tenderness on left side and tumor could be palpated on that side; adnexa did not seem to be attached to tumor. There were no general adenopathy, and the extremities were negative except for local condition. Knee jerks and ankle jerks were not obtained. Clinical and laboratory findings before operation: Temperature on admission 99.2°, which fluctuated only slightly; on morning of operation it was 100°. Pulse, ninety on admission, fairly constant. Urine, pale amber color, specific gravity 1.014, acid reaction, trace of albumin, glucose negative, few hyaline casts, and a few white cells. Blood; total white count 62,000, ninety-three per cent. polymorphonuclears, seven per cent. lymphocytes. Blood pressure, 164/80.

The preoperative diagnosis could not be definitely made, except the very obvious acute abscess in the inguinal region, which it was thought most likely originated from a ruptured strangulated hernia of the Richter type.

The patient was taken to the operating room on the second day after admission, where, under gas and oxygen anesthesia, two incisions were made over the most prominent parts of the abscess. It contained several ounces of very foul smelling, grayish, bloody pus, and about ten to fifteen c.c. of gas. Immediately on making the incision, the patient stopped breathing, and the operation was rapidly terminated with limited exploration of the pus cavity, which, however, seemed to agree with the preoperative diagnosis of ruptured strangulated Richter hernia, with a resulting fecal fistula. Artificial respiration was given, rectum dilated, and stimulative measures used. She began to breath shortly, but her condition was poor on return to the ward.

Postoperative course: The patient slowly regained consciousness and became quite noisy and restless on the second day. On the evening of the second day, she became visibly weaker, quiet, and lost consciousness. Her temperature rose to 101.8° and to 102.6° on the morning of the third postoperative day, when she died.

Postmortem examination: The body conformed to the outline of the physical examination given above, except that the original tumor in the left lower quadrant was not present, but instead, the two operative incisions described. The cavity opened into by these incisions was lined with greenish necrotic slough, the contents having a distinctly fecal odor; on exploration, there seemed to be an opening into the interior, but this could not be definitely ascertained by external examination.

On opening the abdomen, however, there was seen at a corresponding point with the external cavity mentioned above, an anastomosis of the sigmoid portion of the colon, by means of dense fibrous adhesions, with the extraperitoneal structures, i. e., muscle and subcutaneous tissues. These markedly injected adhesions held the sigmoid portion of the gut firmly to the side wall so that now by external examination, a definite sinus from the outside could be demonstrated to communicate with the gut at this point.

Dissection of the sigmoid colon and the immediately surrounding structures showed the upper third of the colon to be the seat of a large, fungating, ulcerating carcinoma, tending to run around the intestine and measuring ten centimetres in diameter. Further investigation and opening of the gut showed the ulceration to occur mostly on the lateral aspect, affecting the surrounding structures, i. e., the quadratus lumborum muscle posteriorly and through the transversus, internal oblique and external oblique so that the lumen of the colon was separated from the exterior by only the skin and subcutaneous structures. This huge abscess pocket was lined by greenish necrotic slough, and portions of fecal material were present in the cavity proper.

The liver was the seat of numerous large, white, firm, metastatic nodules, increasing the size of the organ and rendering the surface very irregular. The largest nodule was in the tip of the right lobe and measured eight cm. in diameter. On section, metastatic carcinoma riddled the liver, there being one growth five cm. in diameter running the entire length of the organ. The liver was congested and presented a peculiar mottled appearance especially marked about the central veins. Microscopic section gave a picture of metastatic adenocarcinoma plus chronic passive congestion and fatty infiltration.

The microscopic picture of the original growth and the metastatic nodules in the liver was that of a typical adenocarcinoma showing distinct evidence of remaining alveolar formation but with some loss of polarity and marked atypical morphology and extensive overgrowth.

The remainder of the examination showed both grossly and microscopically brown atrophy, chronic fibrous myocarditis and atheromatous degeneration of the coronaries in the heart; sclerosis and atheroma of the aorta; chronic interstitial nephritis (arteriosclerotic type) and pyonephrosis of the kidney; senile degeneration and subserous myomata of the uterus; and senile, fibrotic, and cystic degeneration of the ovaries.

DISCUSSION

The occurrence of carcinoma of the sigmoid is not infrequent. Ewing (1) quotes Kaufmann, who found twenty-three per cent. of 123 cases of carcinoma of the colon situated in the sigmoid, and Korte, Petermann, and Anschutz who found forty-two per cent. of 297 cases. Korte (2) reports forty-one per cent. of 254 cases situated in the sigmoid. Judd (3) recently found forty-nine per cent. of 595 cases situated at the sigmoid flexure. Rankin (4), however, states that annular carcinoma is present in only one growth in four in the colon.

Clinically, the patient presented a history of diarrhea over a short period six months previous to admission. She had lost slightly in weight. Otherwise there was nothing to suggest carcinoma of the bowel, and the cardinal symptoms of pain, constriction, hemorrhage, tumor, and general debility were all absent. Handfield-Jones (5) reports a case in which there was not a single symptom to attract attention to the large bowel, in which there was an annular carcinoma of the rectosigmoidal junction, the patient living less than twelve hours after rup-

ture, Ashhurst (6) reports the case of a man fifty-two years of age, who gave no history of any symptoms except a mild constipation until five days before admission to the hospital when he became completely blocked by an annular carcinoma of the sigmoid.

We have been unable to find any record in the literature of a case perforating into the abdominal wall. Madelung's (7) collection of one hundred cases of carcinoma of the splenic flexure presents several which ruptured to result in peritonitis. Schwab (8) and Hartwell (9) report cases in which perforation of the carcinoma resulted in a subdiaphragmatic abscess, and such a case is described in St. Thomas's Hospital report (10) in 1905. Hutchinson and Wolbach (11) report a case in which perforation led to an extensive peritonitis followed by a secondary abscess between the colon, kidney, and spleen. Fawcett (12) reports a case in which the sigmoid flexure became attached to the bladder with the formation of a sigmoid vesicle fistula. Ashhurst (13) reports a carcinoma of the hepatic flexure in which a pelvic abscess formed.

The cases reported in the literature would suggest an infrequent occurrence of distant metastases. Such a view is held by Hartwell (9), and in the hundred cases collected by Madelung (7), the liver showed metastases only six times. Lynch (14) also states that sigmoidal growths remain stationary for a long time. However, Hayes (15) found from experience in one hundred cases of carcinoma of the colon, metastases to the lymph nodes most frequently occurred when the sigmoid was involved. In line with this, Cheatle (16), and also Handley (17), found that carcinoma of the lower bowel extended chiefly by the lymphatics and to a very slight extent in the submucous or in any part of the gut wall.

The Winter's Mastoids*

CLARENCE H. SMITH, M.D., F.A.C.S.
New York

This résumé is based on the records of forty-one consecutive cases in which I operated during the five months' period from December to April. These cases are all taken from my private practice, as I wished to select those of which I had knowledge throughout their entire course.

INDICATIONS FOR MASTOID OPERATION

In a case of acute mastoid involvement, it is most important, and also at times most difficult, to decide when it is no longer safe to watch the development of the case and treat the patient symptomatically, but that an operation is necessary in order to conserve the patient's hearing and perhaps save his life. Several indications may be present, rarely are all found at one time, but generally at least two of them are to be found.

A postauricular swelling, of course, generally means an abscess under the periosteum covering the mastoid. This swelling could only be from one other source, namely, furunculosis of the auditory canal. When that is excluded, the indication for an operation is positive .

A drooping of the posterior superior angle of the bony external auditory canal is the next most positive indication. This drooping is caused by a periostitis at this point, which is the bone covering the aditus leading to the mastoid process, showing the probable condition of the whole of the periosteum covering the mastoid. This sign can be made out with little difficulty, the marked narrowing of the inner end of the canal on the diseased side being in contrast to the more spacious and lofty canal of the normal ear.

Persistent tenderness over the mastoid process is the next most reliable sign. Pain is another symptom which is of importance. This is generally worse at night, disturbing the patient's sleep.

*From the Department of Otology, New York Post-Graduate Medical School and Hospital. Read before the North Bronx Medical Society, May 14, 1925.

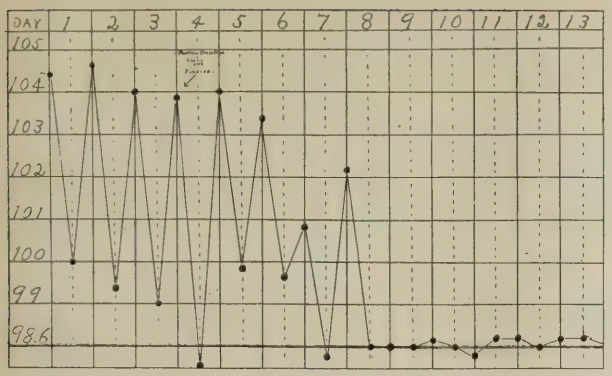

FIG. 1.—Temperature chart in a case of chronic suppurative otitis with acute mastoiditis and lateral sinus thrombosis. (Case I.)

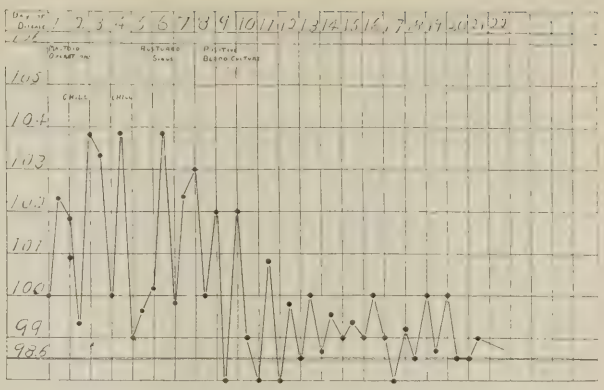

FIG. 2.—Temperature chart in a case of acute suppurative mastoiditis with lateral sinus infection. (Case II.)

Profuse discharge after the first week of an acute otitis is very suggestive of a mastoiditis which should be operated upon. It goes without saying that the pus that comes welling out of these middle ears could not all come from the narrow confines of the tympanic cavity, but is part of the drainage of the mastoid cells. Persistent discharge, which baffles all conservative efforts to dry it up, is an indication that some necrosis of the bone has occurred, and if we are concerned in saving the patient's hearing, the advisable measure is a mastoidectomy.

Elevation of temperature would be an indication for operation if persistent. This is a variable symptom. As a rule it is present in children, particularly in the evening; in adults it is rather the exception to have fever. Marked impairment of hearing of the sound conducting type in a case of mastoid involvement, should be an important consideration.

In the abstract, one may look on the mastoid operation as indicated, first and most important, to save life by preventing the extension of the inflammation to the interior of the cranium; second, to save the hearing, by removing from the patient a bony necrosis which is keeping up inflammatory changes in the middle ear that interfere with the delicate mechanism of the auditory apparatus, and third, to obviate the possibility of a chronic purulent otitis, which is at all times a menace to the health and life of the patient and a very certain cause of irreparable loss of hearing.

CLASSIFICATION OF CASES

The cases in which I operated may be classified as follows: Acute suppurative mastoiditis without complications, thirty-four; chronic suppurative otitis with acute mastoiditis, two; chronic suppurative otitis with acute mastoiditis and lateral sinus thrombosis, one; acute suppurative mastoiditis with lateral sinus infection, four. Of these forty-one cases, ten were in adults, the rest being in children under sixteen years of age. The ages varied from eight months to sixty-five years.

SIMPLE UNCOMPLICATED MASTOIDITIS

The thirty-four cases of simple uncomplicated mastoiditis are rather easily disposed of. They were all somewhat similar and a repetition of their histories would be tiresome. These patients were operated upon on the basis of the clinical picture just depicted, some having one combination of indications, some another. All but one were in the hospital seven days or less. Just as soon as the patients are fever free, we encourage them to get up out of bed for a short period, and at the end of a week they are quite able to help themselves.

The modern method of dressing a mastoid is much more simple and less painful than it once was. My plan is to place a cigarette drain of gauze covered by rubber tissue as far as the mastoid antrum; the replacement of this is barely noticeable.

We keep the mastoid wound open until the middle ear is dry. Some of these cases were completely healed with a dry ear, in two weeks' time from the date of operation. The average period of healing was four weeks. In one case a second operation was necessary before it would heal, an extension of necrosis later than that found at operation I suppose being responsible for this.

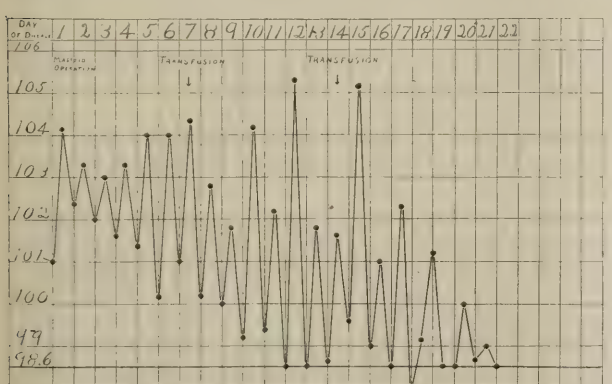

FIG. 3.—Temperature chart in a case of lateral sinus infection. (Case III.)

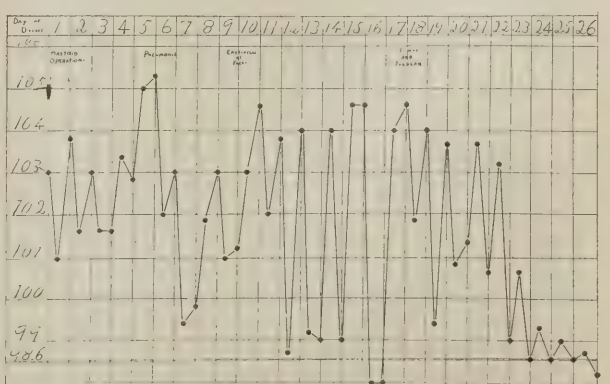

FIG. 4.—Temperature chart in a case of lateral sinus infection. (Case IV.)

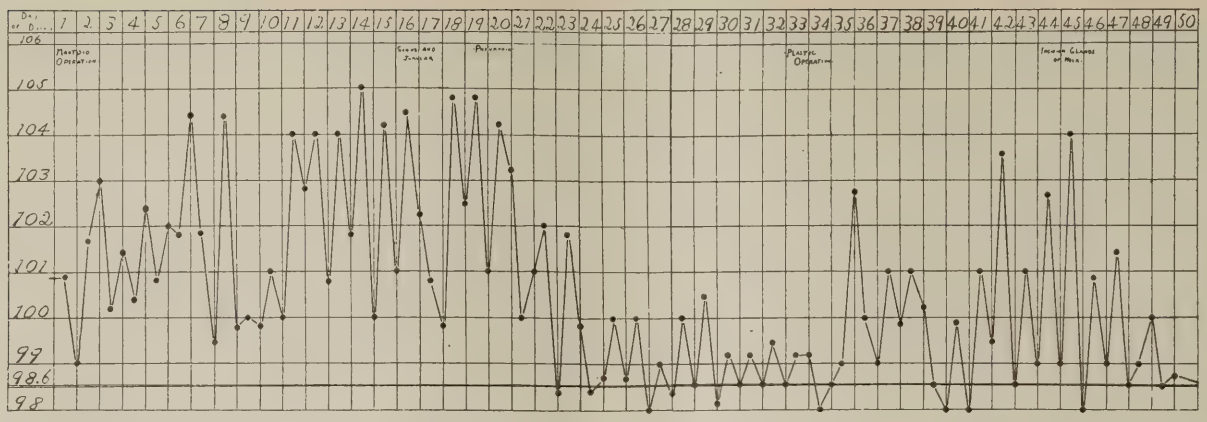

FIG. 5.—Temperature chart in a case of mastoiditis of the hemorrhagic type with sinus operation and jugular ligation on the sixteenth postoperative day. (Case V.)

CHRONIC SUPPURATIVE OTITIS WITH ACUTE MASTOIDITIS

In the two cases of chronic purulent otitis the patients were really fortunate in having acute infection of the mastoids, as they were thus forced to be operated upon and their necrotic middle ears were cleaned up at the same time by the radical mastoid operation.

CHRONIC SUPPURATIVE OTITIS WITH ACUTE MASTOIDITIS AND LATERAL SINUS THROMBOSIS

This was a particularly interesting case.

CASE I.—G. O., aged sixteen, was seen by me at his home in consultation with Dr. Bartels, on January 9, 1925. He had been confined to his bed with a temperature of 100° to 103° for three weeks. His illness had begun shortly after eating some fish, which it was thought gave him gastric symptoms. This was at the time of the typhoid fever epidemic, and a Widal reaction had been taken, which was negative. His symptoms for the most part had been gastrointestinal, he had had no aural pain and no headache. As his left ear had been discharging for several years and the amount of discharge had noticeably been augmented since his illness commenced, I was asked to see him. I found an emaciated youth who showed a profuse aural discharge, some drooping of the posterior superior angle of the canal, and a noticeable thickening of the drum remnants. A slight amount of mastoid tenderness was elicited. I sent him to the hospital the same day for observation and study. His blood was negative for malaria and typhoid, he showed only a moderate leucocytosis and his blood culture was sterile. His temperature had a septic range with daily excursions from normal to 104° and over.

On the fourth day of his hospital stay, I operated on the mastoid and found most extensive necrosis extending into the occipital bone. There was an extensive clot in the sigmoid sinus reaching downward into the jugular bulb. This I cleaned out, and then exposed the internal jugular vein and found it to be collapsed. This was resected to a point above the facial branch. He had a moderate febrile reaction for the next few days, when his temperature reached normal to stay.

The most interesting point about this case was the absence of pain. By the way, the organism found in the mastoid was the Streptococcus mucosus capsulatus, which is notorious for being present in this painless and insidious type of aural case.

FOUR CASES OF ACUTE SUPPURATIVE MASTOIDITIS WITH LATERAL SINUS INFECTION

CASE II.—Mrs. Z., aged fifty-four, was admitted to the hospital, on December 19, 1924, and had a right sided mastoidectomy performed on that day. There was considerable necrosis, the sinus being necessarily exposed. On the third postoperative day she had a severe chill lasting twenty minutes, with a subsequent rise of temperature to 103.6°. A blood culture was then taken; this later showed the presence of the Streptococcus viridans. On her seventh postoperative day she had a profuse unprovoked hemorrhage from the sinus. On the eighth day she showed a phlebitis in the left lower extremity. This was easily enough to account for her fever at that time, which was moderate. So I decided to do some watchful waiting and was rewarded soon by her temperature reaching normal permanently. She was able to leave the hospital three weeks after her operation, of course still with the phlebitis. The mastoid was dressed at her home and she finally was discharged entirely well six weeks after the operation had been performed.

The interesting points in her case were: 1. The chill. Did it come from a septic mural thrombus? 2. The hemorrhage from the sinus. Could it have washed away the thrombus? 3. The positive blood culture, which generally necessitated a shutting off of the infected mastoid focus by ligation of the vein. 4. The phlebitis, which looked as if it were metastatic. 5. Finally, the fact of the subsidence of the symptoms and her complete recovery without further surgical intervention.

CASE III.—This was a case of lateral sinus infection in which recovery took place after two blood transfusions. Geraldine W., eighteen months old, the child of a physician, was operated on for a left sided mastoiditis on April 3, 1925. Her temperature had been high from the commencement of her ear symptoms five days before. In spite of the operation her temperature stayed steadily around 103° to 104° for the next five days. Then it began to take a septic curve 100° to 104°. On the seventh day, the blood cultures being sterile, I had Dr. Tracy

Fisk transfuse her with 115 c.c. of her mother's blood. This seemed to have a good effect, the temperature dropping considerably for three days, when it began again to steeple between 99° and 105° for four days. We then had her transfused with another 100 c.c. After one more septic excursion the temperature came down by lysis and she was discharged from the hospital three weeks from the date of her mastoid operation, in good condition. I am confident that the transfusions in this case turned the tide and gave the patient enough complement with which to fight the sepsis from which she was suffering.

Case IV.—This was a case of lateral sinus infection with no demonstrable clot on operation, which was brought to recovery by ligating the internal jugular vein.

Isabel K., two years old, had a leftsided mastoidectomy on January 30, 1925. She ran a fairly high postoperative temperature which was explained by finding pneumonia on the fifth day. This complication cleared up, to be succeeded by facial erysipelas. On the eleventh day the temperature began to steeple and continued to do so, until on the eighteenth day I again operated on her, exposing the internal jugular vein, which I found surrounded by periphlebitis. I ligated the vein above the facial branch, and explored the sinus but found no demonstrable clot. After a few more days of fever, the temperature curve reached normal. She left the hospital twenty-six days after her mastoid operation, and shortly afterwards was discharged with her wounds healed and the ear dry.

Case V.—This case was similar to Case IV. E. D., four years old, was operated upon on November 17, 1924, for a leftsided mastoiditis. Her case has been reported elsewhere. Suffice it to say here that it was a hemorrhagic type of mastoiditis, showing high temperature from the outset, with a sinus operation and jugular ligation on the sixteenth postoperative day, then pneumonia, then cervical adenitis with operation. She finally left the hospital in good condition after a sojourn of fifty days.

Prolapse of the Female Urethra

Report of a Case

ADOLPH JACOBY, M.D.
New York

Prolapse of the urethra in the female, although not a rarity, is of such infrequent occurrence that cases are of sufficient interest to warrant their being reported. The condition may occur at any age, though it is stated that most cases occur in children. The cause is not always clear. When preceded by a dilatation of the urethra, with more or less relaxed mucosa, in women with lax vaginal walls, it is conceivable that strain or exertion or trauma may cause the mucosa to roll out and present beyond the external meatus. In children with no such predisposing causes, it is hard to understand how the same exciting factors will bring about this result, unless there is some developmental or nutritional deficiency in the attachment of the urethral mucosa to the underlying structures This is probably the condition that exists in cases occurring in children, as well as in chlorotic and debilitated women. Long continued congestion and irritation of the urethra favors its occurrence.

The prolapsed membrane may retain its normal color for a time, but soon becomes deep red or bluish due to the partial strangulation of the tissue. The normal appearance is retained for a longer time when the urethra is dilated and the external meatus is wide.

The condition must be differentiated from other projections from the external meatus such as urethral caruncle, new growths of the urethra, and prolapse of the bladder through the external meatus. This can be readily done when it is understood that in prolapse of the urethra the entire mucosa is rolled out through the meatus, so that on separating the labia a deep red tumor with a slit in the centre representing the orifice of the urethral canal is visible. In urethral caruncle the projection is from one aspect of the meatus, and in new growth the urethra surrounds the growth instead of being in the centre. In prolapse of the bladder through the urethra, there is no orifice in the projection and a sound will determine the origin of the prolapsed portion.

The case here reported occurred in a school girl seven years old. One year ago she had pneumonia and had been well since. The child stated that she was kicked in the vulvar region two weeks before any symptoms were noted. Four days prior to consultation she complained of an itching and burning in the vulva and a smarting on urination. The mother noticed bloody stains on the child's underwear. There was no interference with or frequency of urination and no marked discomfort. The presence of the blood stained underwear led the mother to bring the child for examination.

A general physical examination revealed no abnormalities. On inspection of the vulvar region, a deeply congested mass was visible occupying the whole space between the labia, overlapping and hiding the hymen. This mass had an irregular longitudinal slit in the centre, was slightly eroded at one portion, and was exquisitely sensitive, bleeding readily on being touched with a cotton tipped applicator. On passing a catheter through the orifice, clear urine was withdrawn.

An attempt was made to replace the prolapsed membrane by applying to the mass a solution of two per cent. novocaine containing five minims of adrenalin to the ounce, to overcome the sensitiveness and shrink the congested tissue before trying to push the

everted membrane back into the urethral canal. This was found to be impossible. The child was then put to bed, and continuous applications of a solution of alum acetate were used in the hope of reducing the size of the mass and so permitting reposition. This also failed. After two days of this treatment operation was performed under a general anesthetic.

The operation consisted of excising the prolapsed portion and approximating the cut edges by interrupted sutures. A retention catheter was inserted and left *in situ* for two days. After its removal the patient voided without pain or difficulty. Pathological examination of the tissue removed showed the presence of subacute inflammation.

Two months after the operation, an examination showed an external meatus which appeared normal, there being no evidence of narrowing of the meatus, or recurrence of the prolapse. At no time since operation has there been any urinary complaint.

A New Method (Cultural) in the Treatment of Chronic Suppurations, Particularly of Bones

MAX THOREX, M. D.

Chicago

The method of treatment of chronic suppurative processes, especially of bone, by a compound of the nitrates of aluminum and potassium has now received an extended trial at the American Hospital (three years); and the results have been observed in a sufficiently large series of cases (about 146) of all degrees of chronicity and severity, to warrant definite conclusions regarding the value of this method.

Details concerning the preparation of aluminum-potassium nitrate compound have been already published (1). Succinctly, the compound has been devised for the purpose of utilizing the wellknown oxidizing properties of potassium nitrate, while at the same time avoiding its macerating and irritative properties. The nitrates of potassium and aluminum are combined in the proportion of the molecular weight of one molecule of aluminum nitrate to three times the molecular weight of potassium nitrate. These are dissolved in hot nitric acid and a double salt crystallizes out on cooling which contains thirty-one per cent. aluminum nitrate, forty-four per cent. potassium nitrate and twenty-five per cent. waters of crystallization.

The product is neither a bactericide nor a germicide. It has been determined experimentally (and verified clinically) that it really assists and intensifies the growth of bacteria (Fig. 1). Its therapeutic value, therefore, is based upon an entirely different principle than those of ordinary antiseptics and of the dyes which aim at inhibiting the growth of bacteria.

Aluminum-potassium nitrate can be used in the treatment of any deepseated chronic suppurative process, but it is, perhaps, especially effective in processes with a discharging sinus, such as an old chronic osteomyelitis. We have employed it not only in osteomyelitis but also in tuberculous bone abscesses, carbuncles, furunculosis, various wound infections, gangrene, and other conditions..

Therapeutically the nitrate compound is used in a medium of sterilized rolled oats and is applied directly to the skin over the affected area without the interposition of gauze or any other medium. The dressing is renewed as soon as it becomes saturated with secretions (at least once in thirty-six hours).

The characteristic effects of the application are first, the appearance of an erythema manifest within forty-eight hours. This is followed later by the appearance of vesicles and pustules containing purulent fluid, these vesicles being limited to the skin covering the underlying suppurative area. This reaction continues as long as infection persists in the underlying tissues. When the pathological process is cured, no further reaction will take place. In other words, if the dressing is applied over a normal area

the typical reaction does not occur. The characteristic reaction is especially marked in cases of osteomyelitis with a discharging sinus. Here a thin serous discharge is soon converted into a marked purulent discharge containing vast numbers of polymorphonuclear leucocytes, even before the appearance of a skin reaction.

The phenomena just described suggests that the mode in which the aluminum-potassium nitrate compound acts is by dialysis through the skin. Some element from the dressing must dialyze through the skin to the deeper tissues and call forth an increased leucocytosis expressed in terms of a voluminous pus

discharge; and, as a matter of fact this was proved experimentally before the clinical applications of the compound. There is a rapid autolysis and liquefaction of the pathological products within the diseased area. This is to a great extent due to the action of nascent oxygen on the diseased tissues. The nascent oxygen is probably derived from the splitting of the nitrate ion in its passage through the skin to the deeper tissues. The nascent oxygen does not alter normal healthy tissues, however, but tissues infected with organisms are attacked by the compound which accounts for the selective action of this preparation in acting only on diseased structures.

Perhaps the most significant therapeutic action of the compound, however, is that exerted on bacteria. It has previously been mentioned that the action is not bactericidal. Apart from the fact that the compound only produces a reaction where pathogenic organisms are present there is also an increased bacterial count in the exudate during the initial period of treatment, but the important fact is that the virulence of the organisms is reduced in proportion to their increased rate of propagation. I have, therefore, named this method the cultural method; for the body of the patient is the host for cultural propagation of the invading organisms. The effect of this is at the same time to reinforce the resisting elements of natural defense as evidenced by the increased leucocytosis and phagocytosis. The rapid autolysis at the site of the lesion gives relief by the rapid elimination of noxious products, which were absorbed prior to the institution of the treatment, so that a secondary systemic reaction follows expressed by a betterment of the general state.

Total number of cases treated	116
Total number of cases discharged cured	70-60 per cent.
This does not include cases still under treatment	
Cases discharged improved	10-9 per cent.
Cases in which no change was noted	17-14 per cent.
Cases still under treatment	19-18 per cent.
Average duration of treatment	11 1-3 weeks
Age of patients—youngest 2½ years—oldest 76 years.	
Sexes—males, 64	55 per cent.
females, 52	45 per cent.
Period—September, 1922 to September, 1924.	
These cases were not selected but accepted as presented.	

Since the initiation of this treatment at the American Hospital of Chicago, more than one hundred cases of chronic suppuration of various kinds have been submitted to it. Approximately half of these were mixed infections, the predominating organisms being the staphylococcus aureus, the streptococcus, the bacillus pyocyaneus and various saprophytes. The lesions included osteomyelitis of various grades of severity both traumatic and hematogenic, bone tuberculosis in which secondary infection was an added complication, furunculosis, gangrene and various postoperative wound infections. Many of these were old and inveterate cases which had resisted surgical and other treatments. In some cases the indication was frankly for surgical operation and the aluminum-potassium nitrate treatment was applied as a preliminary to such treatment, but it was a remarkable experience to find that in a large number of such cases the results obtained from the nitrate dressing were such as to obviate any further surgical treatment.

FIG. 3a.—B. R., Case 746. Female, age seven years. Osteomyelitis of second metatarsal. X ray taken at time of beginning aluminum-potassium nitrate treatment, October 27, 1924.

FIG. 3b.—B. R., Case 746. After one month's use of aluminum-potassium nitrate treatment, November 25, 1924.

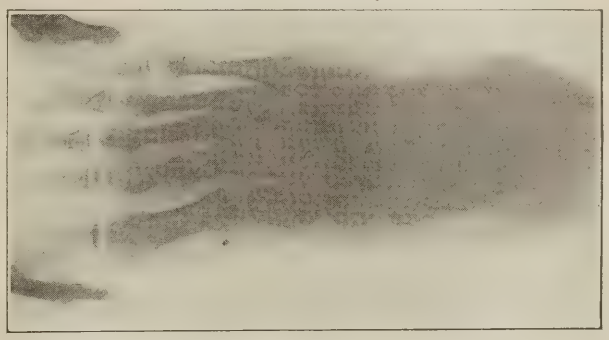

FIG. 3c.—B. R., Case 746. After two months' use of aluminum-potassium nitrate treatment, December 26, 1924.

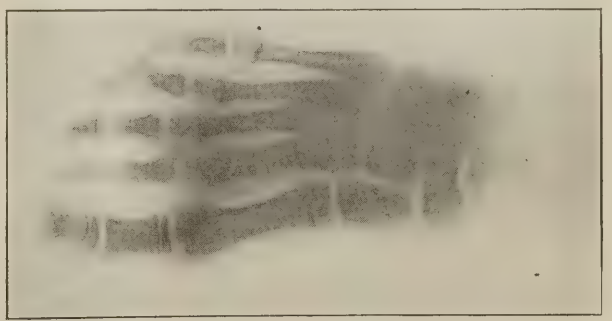

FIG. 3d.—B. R., Case 746. After three months' use of aluminum-potassium nitrate treatment, January 27, 1925.

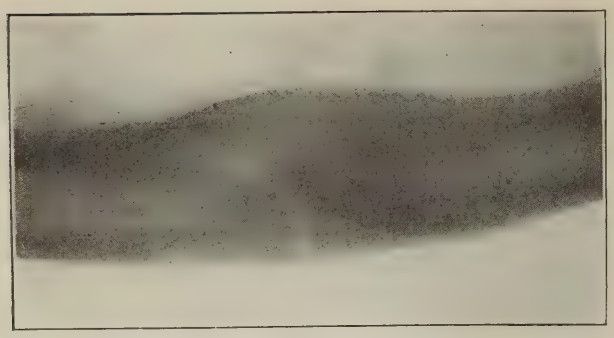

Fig. 4a.—B. M., Case 751. Male, age twenty-four years. Osteomyelitis of femur at site of former fracture (two years earlier). Note defect in callus. September 15, 1924.

In more than seventy-five per cent. of this series of cases the patients became ambulatory and able to pursue their avocations, coming to the hospital only for dressing, and at least fifty per cent. were clinically cured (Fig. 2). These results are strikingly remarkable when they are contrasted with the results obtained by surgery alone in the past. The repeated

Fig. 4b.—B. M., Case 751. After sixty-one days of aluminum-potassium nitrate treatment. Note clearing up of callus defect. November 15, 1924.

surgical operations, long hospitalization, loss of employment and invalidism with the attendant expense and discomforts have been obviated.

I do not mean to imply that the aluminum-potassium nitrate treatment is indicated as a substitute for rational surgery when this is clearly called for as in acute fulminating types of infection; nor that it

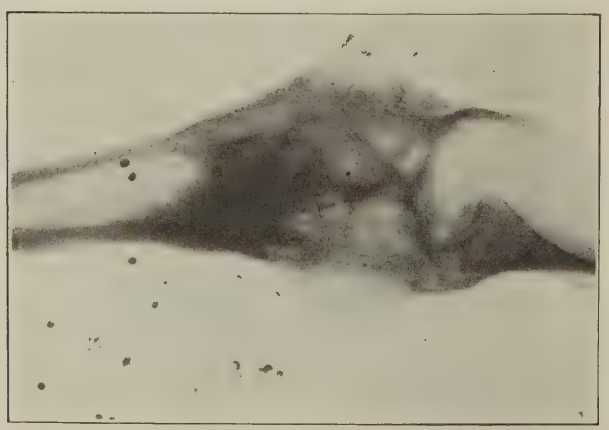

Fig. 5a.—L. C., Case 696. Female, age forty-three years. Osteomyelitis of left knee (gunshot wound eight years earlier). X ray taken at time of beginning of aluminum-potassium nitrate treatment. Note buckshot in soft tissues. March 5, 1924.

will always preclude surgical interference in chronic cases, but the treatment is indicated, either as a preoperative or postoperative procedure, in all badly infected cases especially of the chronic type, and it is particularly applicable to these cases which have

Fig. 5b.—L. C., Case 696. Appearance at time of beginning aluminum-potassium nitrate treatment. March 5, 1924.

resisted surgical and other treatments. As in my own series of cases preoperative treatment will, I believe, very frequently obviate operation and when operation must be carried out it will be under better

Fig. 5c.—L. C., Case 696. Appearance after two months of aluminum-potassium nitrate treatment, May 4, 1924.

conditions and the postoperative course will be greatly shortened.

In conclusion (and these conclusions are borne out by other investigators who experimented with the method clinically, notably Strauss, Kreuscher and

Sherman) I am convinced that with this form of treatment chronic suppurative conditions will often yield excellent results. In frankly surgical cases (acute osteomyelitis) the treatment is a powerful adjuvant in rendering the surgical procedure more efficacious. (Figs. 3a and 4b).

A few illustrations are given to show the clinical course of lesions under this treatment. These illustrations need no explanation as they fully convey their own story; they are fairly typical of the general run of cases treated.

AMERICAN HOSPITAL.

Interrelationship of Physician and Dentist*

M. L. RHEIN, M.D., D.D.S.
New York

The paradoxical relations between medicine and dentistry have been the theme of discussion at many dental meetings during the past few years. The earnest and sincere discussion of the existing state of affairs has been educational, and therefore provocative of much good.

In furtherance of this enlightening propaganda, I wish to present some of the dental aspects of this question.

The teeth, gums, pericementum and other dental structures are part of the body, nourished and controlled by the same general factors which similarly provide for the remainder of the body. Notwithstanding these facts, the degree of doctor of medicine is conferred without imparting to the recipient anything like a proper education in the anatomy, histology, physiology or pathology of the dental tissues. With such a hiatus in the medical curriculum, it is impossible for the recent graduates properly to differentiate between good and bad dentistry. All praise to the few physicians who, realizing this great defect in their education, have taken the time for intensive postgraduate study of dentistry. However, the number of such physicians is so few that we can discuss this subject without considering this minor element.

The physicians who specialize in nose and throat, eye and ear, genitourinary diseases, etc., after a grooming in general medicine, devote their entire time to portions of the human body that have no closer relations to health and disease than does stomatology.

In every medical college, the underlying principles of the physiology and pathology of these other specialties are not only taught, but the student must pass an examination on practically every specialty except dentistry.

In 1909, at the meeting of the International Medical Congress in Budapest, it was my great pleasure to visit one medical school which met this essential. The medical department of the University of Hungary requires the medical student to take a twelve weeks' course in the principles of dentistry and subsequently to pass a satisfactory examination in the dental department of the university. This does not, however, entitle him to practise dentistry. For this purpose he must graduate from the dental department, the curriculum of which compares most favorably with those of our own dental schools. In order to matriculate for this course he must, however, first be a recognized graduate in medicine.

This belittlement by medicine in our country of the importance of the dental tissues and organs is largely due to the fact that our dental colleges graduate men in dentistry who do not possess the degree of M.D. They endeavor to compensate for this by teaching the dental students the principles of general anatomy, physiology, embryology and pathology from the dental viewpoint. This not only falls far short of the needed education, but has brought about such differences in nomenclature as to make it often difficult for the dentist to make his pathological terms understandable by the physician. They do not speak the same language. This must be the real reason why the physician so rarely calls the dentist into consultation, whereas if the heart or the throat, or the eyes, were the seat of disease, the family doctor would ask the service of one specializing in one of these fields.

However, the dental curriculum is improving rapidly, and while it may still fall short in many essentials, the failure of the physician to seek dental consultation in dental cases constitutes no palliating circumstance. The community at large suffers greatly by this neglect of those whom the law has recognized as qualified to alleviate suffering, to prevent further disease, and to cure dental lesions.

During the past few years physicians have commenced to recognize many diseases resulting from dental focal infections. At first glance it would seem in the light of these developments that the doctor would see the importance of dental consultations.

In my early practice in the 80's and 90's, the difficulty of obtaining a proper consultation with the family physician worried me greatly. They had a unique way of resenting a dentist endeavoring to add to their dental education, even though he might be a regular M.D. who had given ample time and study to the general practice of medicine. With the great hope of causing the physician to seek out the dentist for consultation in dental cases, I kept on showing the possibilities of arthritis, nephritis, diabetes, heart lesions, and other conditions starting from dental focal infec-

*Read before Kings County Dental Society, January 29, 1925.

tions. In June, 1896, I published in the *Dental Cosmos,* "The Oral Expressions of Malnutrition," which in the clinical notes of various cases showed where disease of the mouth was the result and not the cause of constitutional derangement.

When finally the value of the x ray came to be recognized as a diagnostic factor, we hoped that now surely the family physician would come to the dentist for consultation and for a correct interpretation of the picture as it bore on the jaw and its adjacent parts. You all know that, on the contrary, when diagnosis is obscure, the doctor, instead of having the dentist examine the patient, sends him to an x ray laboratory and absorbs the interpretation and advice thus sent by men as little fitted to interpret the röntgenogram in these situations as is the doctor himself. As a result, thousands of teeth which should have been saved have been extracted.

The County Medical Society of New York is giving weekly lectures this year on the value of early diagnosis of grave diseases. In this course are interspersed lectures by specialists, showing the effect of commencing deviations from health in their respective specialties. There is, however, in the course no provision for consideration of lesions of the dental tissues, and yet I say without fear of any serious logical denial that the changes in the macroscopic condition of the gums make this region a highly valuable diagnostic aid in the earliest periods of disease.

The time has arrived when this breach between medicine and dentistry must be healed. Meetings like the one this evening have failed to accomplish this object. What shall we do? Must the dentist resort to publishing this incongruousness in the public press? It is my firm belief that some such severe remedy must be applied to insure to the public the meed of attention which the doctor should accord the dentist when the former has to deal with dental disease, real or imaginary.

Let us consider in detail the different values that arise from a medicodental consultation. They naturally present a different aspect, viewed on the one hand strictly from the side of the medical practitioners, and on the other strictly from a dental viewpoint. It will be our part of this program to take up these different points of interest and present them more especially from the dental viewpoint.

It has always been admitted that the greatest values in every department and branch of medicine are to be found in what is known as preventive medicine. In this respect dentistry has long since coincided, and the efforts of the dentists in preventive dentistry have received the attention of the brightest minds in our specialty.

In considering this aspect of the case, our first thought must lead us to the promulgation of data for improvement in the teeth of future generations. The result of all of our research work in regard to the etiology of caries of the teeth leaves us today with a positive conviction that the general nutrition of the individual plays an important rôle in this respect. We know that teeth that are erupted with enamel in which no defect can be found are in the best state of defense against caries. We know, furthermore, that for the production of such teeth it is essential that the diet should be of such a nature as to carry with it the proper modicum of inorganic material that is found in the makeup of the teeth. As the formation of the teeth proper commences many months before birth, the attention of the observant and scientific dentist has been always directed more or less towards the prenatal diet of the mother. This question is also receiving the careful attention of the physician. The result of this care is seen today in that the child whose mother is under the care of an up to date physician has better teeth, and no inclination to rickets. The literature of dentistry shows that this subject was considered in its present accepted manner long before it was seriously taken up by the physician. The large percentage of rachitic children has brought about a study of this subject which has insured a more scientific diet to the pregnant woman. As a result the percentage of children under such care who displayed a tendency to rickets has decreased perceptibly. This diet consists in a proper amount of lime and phosphates to be taken in the food of the mother. Whatever tends to the decrease of a tendency towards rickets necessarily tends to a better dental structure for the child. The two conditions go hand in hand, and in this respect there can be at the present time no difference between the physician and the dentist.

Forty years ago there was a large class of medical practitioners who were deliberately depriving mothers in their prenatal diet of lime and phosphates in order to obtain an easier and less painful delivery at childbirth. They were deliberately advising procedures in diet resulting in the birth of children whose osseous framework and tooth structure were starving from lack of inorganic material. There is no doubt that some of this form of advice is still being given and every effort should be made to stamp it out effectually. To the sane, medical mind, practice such as this is positively nothing short of criminal.

A correct dietary regimen should be followed up from infancy through the entire formative period of a child. The growth and development of the child in normal condition is coequal in all of its parts. Both the baby teeth and the permanent teeth, as well as the alveolar structure in which they are imbedded, develop in the same ratio and proportion as the rest of the body when the machinery of the human mechanism is working in a normal manner.

During the first eighteen months the baby obtains its requisite amount of inorganic material in the milk contents. From that period on, the value of cereal foods in the child's daily ration cannot be overestimated. The enormous increase in cereal foods in the past few years illustrates how vast an improvement has been reached in child nourishment as compared with years ago.

In addition, we must not overlook the value of plenty of sunlight, orange juice, and as the child grows the need of foods containing sufficient vitamins. The science of the child's dietary is so well understood today that there is no excuse for the starving children of thirty-five years ago whose

death certificates bore the incorrect report of death from rheumatism.

In 1886, before infantile scorbutus had been established as the correct term instead of rheumatism, the parents brought to my office a boy aged eighteen months. The enamel had been entirely lost from the four upper incisors. The gums were a cherry red, soft and flabby, and there was a profuse discharge of pus from the gums. The pulps of all four incisors were exposed, and the child was consequently in constant agony. The handling of the arms or legs caused additional screams of pain. Could the pulps be removed? "Certainly," I replied, "but that will not save the child's life. Why not seek the cause of this lack of nutrition?" After a most thorough examination, I found that the diet consisted solely of what was known as Swiss prepared cream. This was at once stopped and pasteurized cow's milk, not too rich at the start, orange juice four times in twenty-four hours, together with a well simmered barley broth carefully strained, was fed the child. Under chloroform the pulps of the four teeth were removed. Recovery was rapid. This patient is now a man of fine physique, with a full set of fairly normal teeth of excellent structure.

Wherever, from congenital causes, the child has rickets or a tendency to rickets, it is certain that the structures of the teeth are suffering commensurately. In addition to the cereals, the use of codliver oil, which has been so advantageous in rickets, becomes equally helpful in improving the tooth structure of the child.

The importance of keeping the deciduous teeth in a clean, healthy state, free from caries, is no less great than the care we should bestow on the permanent teeth.

The real importance of this ideal care of the deciduous teeth is not only not appreciated by the average physician, but also by the average dentist. During the developmental period of the child, everything tending to interfere with nutritional conditions leaves a marked effect upon that particular stage of the dental tissues. Any type of disease peculiar to children leaves such an indelible imprint upon the jaws and is the cause of perhaps stoppage in development of a part of the jaw, or lack of laying down of enamel substance to such an extent as to at once direct the attention of the dentist to the fact that something is radically wrong and that it is now his duty to call the attention of the physician of the child to the necessity of a thorough physical examination. It is this stoppage of development of the alveolus that is at the bottom of almost all of the irregularities of teeth which occasion so much distress and necessitate so much professional service later on.

In like manner, excessive deposits of calculi are at once a marked indication of insufficient elimination. In children between the ages of six and ten it is not uncommon to find an extraordinarily large amount of salivary calculus on the lingual side of the lower incisors. This heavy incrustation is an absolute indication of an acute nephritis which is impairing the eliminative properties of the kidneys, so that we obtain this marked increase in elimination through the salivary ducts. By means of proper treatment this is easily cured in children and consequently it is of the utmost value for the dentist to call attention to such a condition of affairs.

Any impairment in the circulation at the outset leaves an imprint in the shape of some form of diversion from the normal appearance of the dental tissues. This is due to the fact that the circulation which nourishes the dental tissues is by far the most extensive capillary circulation in the body. On this account it is important that the dentist with his keen powers of observation and differentiation of color and form, should make himself so thoroughly conversant with the appearance of normal dental tissue that he can immediately detect the slightest change from normality. As a doctor of the teeth, he should so train his mind as to fix the dental organs as part of the entire organism, and to assume that it is one of his greatest duties to his patient to inform the physician who has charge of the general health of the patient when he observes that something in the circulation has made an abnormal imprint upon the dental tissues.

The dental tissues as an absolute index of any diversion from health is by no means confined to youth. What is still more significant is that different abberations from normal leave different impressions upon the dental tissues, so that we have in the mouth a means of diagnosing the incipiency of many types of disease, if we only have the ability to correctly interpret their different expressions on the gums, the alveoli, the teeth, the salivary glands and the mucous follicles. The well known blue imprint on the gums is diagnostic of the administration of mercury being carried to a point of toxicity. This has been recognized in medicine for more than a century. If the practitioners in medicine had not ceased to make a study of the dental tissues, they would have long since realized the remarkable diagnostic value possessed by the eye of the experienced practitioner in a proper mouth examination.

In tuberculosis of the lungs, which is perhaps the most noteworthy of all diseases for its debilitating effect on the system, the mucous follicles which in health are quiescent and nonapparent, become extremely active. Their action can be compared to that of the sweat glands, only this activity starts up long before it is noticeable upon the derma. At the beginning of tuberculosis these follicles begin to excrete a fluid, and as the disease progresses this excretion becomes more and more excessive, keeping pace, as it were, with the inroads of the infection upon the lung tissues.

In diabetes the gum tissue around the necks of the teeth at once degenerates into a spongy condition which bleeds very easily, and which fails to react properly to surgical measures. This marked degeneration of the gum tissue manifests itself in various types, according to the character of the diabetes and the stage of the disease.

In nephritis there is a condition present that is almost the opposite of this. Here we find a tendency to a line of hypertrophy of the gum. Following the scalloped margins of the necks of the teeth on their lingual surface, the color of the gums becomes blanched in exact contradistinction to the intense redness which so markedly distinguishes its condition in diabetes.

When the heart fails to act in a normal way, it leaves a characteristic imprint on the gum. If there is a lack of oxygenation, it is at once apparent in the intense ruby colored condition of the entire gum surface. On the other hand, when the heart lacks its normal amount of pumping capacity, we find a distinct line of demarcation about one eighth inch above the necks of the teeth. The portion of gum approximately one eighth inch from the necks of the teeth has a pulplish hue, due to the inability of the capillaries to empty properly into the venous system. Above this line, in marked contrast, is seen the normal gum tissue with its pale pink color.

It is hardly necessary to speak of the diagnostic value of the mouth in syphilis because the specialists in this line have been compelled to recognize the same and consequently the mouth symptoms of lues have been more or less taught to the physician.

The undernourished pregnant mother invariably shows one or more erythematous patches on the lingual surfaces of the jaw.

All of these values have been but faintly studied and constitute a wonderful field for future research.

IMPORTANCE OF THE EARLY DIAGNOSIS OF DISEASE

The earlier a disease is diagnosed, the better the physician is able to render aid. If there were nothing else to be said upon the subject, the possibility of the recognition of the very beginning of different types of malnutrition by an intelligent observation of the mouth, should make free consultation between the observant dentist and the family physician something of such vital importance that it would be freely sought by the physician and generously tendered by the dentist.

It is not only a question of the dentist's being able to bring to the attention of the physician that a certain disease has started, but there remains in all these cases the question of what dental operations are feasible and under what circumstances certain dental procedures should not only be postponed, but are at times absolutely prohibitive. While there frequently exist different opinions as to the advisability of certain operations when the health of the patient is impaired, it is almost impossible to set down any well defined rule. Each case must be considered by itself, and this can only be done satisfactorily through the intelligent cooperation of the dentist and the physician.

While it is conceded that a great deal of harm is unquestionably done by dentists when the patient is laboring under the stress of different types of disease, there is another side to this question. Too often physicians peremptorily forbid all kinds of dental interference without an intelligent discussion of the subject with the dentist, whereas if consultation had obtained it would be determined that the dentist by performing certain operations could be of material aid to the physician. Too frequently during the progress of some curable disease the patient emerges with a set of teeth badly impaired by dental neglect during the course of such disease. The value of a healthy mouth with healthy teeth, properly functioning, is greatly underestimated by the majority of medical practitioners. It is of paramount importance, after a cure is effected, that the individual should be able to resume his method of living with his mouth in such a condition that his health can be properly maintained. The field of surgery is strewn with myriads of teeth that have been ruthlessly and unnecessarily removed, an irretrievable loss to the individual in maintaining a proper condition of general health.

When the mouth becomes infected, the physician should freely consult with the dentist as to procedure. Too often a beautiful face has been marred unnecessarily by permitting an alveolar abscess to open externally, yes, sometimes deliberately encouraging its external exit where the etiology of the condition has been entirely overlooked. It may not be amiss to call attention to the strong tendency among a certain class of practitioners to let no patient escape from their office into that of some other practitioner. These men frequently treat fractures of the jaw and minor mouth conditions. When they do no serious injury it is a matter of pure good fortune. The field of oral surgery is one that is well defined, and should be left to the man who is qualified by study, application and experience to obtain the best result in this particular character of work. Often the dental field approximates that of some other specialist. Under such circumstances, if the best interests of the patients are to be considered, the two men should work harmoniously together.

A PROPER UNDERSTANDING OF MOUTH INFECTION NECESSARY

There is nothing that should be more clearly understood by the physician than mouth infection; unfortunately this is not the case. Mouth infections cover a variety of conditions that vary so greatly in their etiology, symptomatology and prognosis, that it is impossible for even the average dentist who is not a physician to have a correct understanding of all of them. How then is a physician not versed in the mouth to have a proper comprehension of them? For instance:

The term "dental focal infection" is used in a very indifferent, if not to say ignorant manner, by a great many physicians, and also by some dentists. A dental focal infection can be best described as a circumscribed infected area in the alveolus which has no drainage. This is in exact contradistinction to the ordinary classic alveolar abscess and different types of mouth sepsis that generally come under the head of pyorrhea alveolaris, as generally understood by the physician, and is spoken of as periodontoclasia by a great many dentists. In the alveolar abscess and in different types of perioclasia (or pyorrhea alveolaris), pus freely exudes into the mouth and is more or less swallowed by the individual and passes through the alimentary canal. While it has a more or less irritating effect upon this tract, and while a certain proportion of it may be absorbed, it can never be considered as dangerous to life itself.

The dental focal infection is located in the alveolus around the ends of the roots of the teeth. This infection is of so low a grade of inflammation that it never reaches the stage of suppuration. On that account there is an absolute absence of pus. The pathogenic organisms, however, keep on manufacturing toxins which are continuously absorbed by the circulation. It is only the inherent resisting forces of the patient thus affected which combat the

insidiousness of this infection. Unrecognized and untreated, it becomes only a question of time when it ceases to be local. One or more of the vital organs is invaded with disastrous results. In other words, dental focal infections may be the cause of heart disease, of nephritis, of diabetes, of arthritis, of appendicitis, or other conditions. The enumeration of this list is only limited to all of the diseases that can be caused by continued toxemias of a low grade. Perioclasia (or pyorrhea) on the other hand is never the direct cause of any of these diseases. We may have a dental focal infection which has produced nephritis, or diabetes, from which in turn has resulted a distinct pyorrhea alveolaris, but the pus exuding from the gums in these cases never has had any connection with the etiology of the nephritis, but is simply a symptom of this disease. This cannot be too strongly emphasized because it is so often misapplied and is so frequently confused by the physician with dental focal infection; and yet in the proper handling of the patient it is of the utmost importance that the differentiation should be well known. A great many physicians, when they see pus in the mouth, have a way of referring to it as pyorrhea alveolaris, and of telling the patient: "You had better see a dentist and tell him you have pyorrhea."

CASE REPORT

A case occurring in my practice some twenty-five years ago may be apropos:

CASE.—A woman over fifty years of age, fell down a flight of steps and struck on her face with a great deal of force. A few days later, her physician finding her mouth overflowing with pus, sent for a prominent surgeon. He examined her mouth and said to the physician: "What was the use in sending for me? This is a case of pyorrhea. Turn her over to a dentist." Upon examining the patient I found a remarkable case of comminuted fracture of the jaw. I say remarkable because when I got through picking out the fragments of jaw bone that was fractured, there were between four and five hundred pieces of bone. This was the cause of the great amount of pus, and when these fractured alveolar fragments were all cleaned out, the pyorrhea was cured.

Knowing the surgeon as well as I do, I am convinced that he unwittingly allowed a patient to pass through his hands which he would only too gladly have attended to had he made a correct diagnosis.

EVILS OF INCORRECT INTERPRETATION OF RÖNTGENOGRAMS

Friction between the dentist and the physician of late has been created by the tendency of the physician to have the mouths of his patients x rayed by the dental laboratories, most of which are run by medical men and others who have no dental training, and who furnish the physician with not only a dental interpretation of the röntgenograms, but with advice as to procedure as well. This has unquestionably resulted in the unnecessary loss of thousands of teeth, which means the ruthless interference with the proper function of perhaps the most important part of the nutritional system of the body. Serious attention should be paid to the correction of this evil affecting the community. When it becomes a question of investigating the condition of the mouth by means of the x ray in order to endeavor to make a correct diagnosis in obscure cases, it should be the bounden duty of the physician to call into consultation the dentist of the patient. The dentist should be asked to furnish proper röntgenograms, and his opinion of them should be given in a consultation that should carry with it the same significance that a consultation with any other specialist would convey. Where the patient has no dentist and the physician desires the aid of the x ray, he should at least see that the patient goes to a laboratory where a properly trained dentist can furnish him with the röntgenograms, and their interpretation. It then rests with the physician to determine if he is satisfied with this laboratory interpretation, or whether it should be fortified by other dental consultation.

The physician is able to advise, see and treat fifteen to twenty people, occupying a span of time during which the dentist may be doing some simple ordinary service for one individual. The average physician has but a poor concept of the amount of time which the dentist gives to each individual case. It is unquestionably true that a certain type of man becomes a charlatan in any branch of medicine, whether in dentistry or some other specialty, and will take advantage financially of his patients in the same manner that a crook operates. This is no excuse for the frequent criticism made by medical men in regard to the fee of certain dentists concerning the value of whose services they are wholly ignorant.

Frequently I have heard medical men of a very high type make these criticisms, where if they knew the amount of time conscientiously occupied by the dentist, they would realize how unjust have been their accusations. Good workmanship and valued service in dentistry is more frequently underpaid than overpaid.

CONCLUSION

No matter what a man's vocation or profession, proficiency is only possible through basic knowledge and through opportunity practically to exercise the same. The more the dentist knows about medical principles and medical practice, the better he will be able to serve his patients. By a parity of reasoning, the more the medical doctor knows about dentistry, the better he will be enabled to recognize obscure conditions due to faulty dental conditions. In the present stage of the practice of these two branches, the dentist knows too little of medicine and the physician is too unfamiliar with dentistry. To obviate the conditions resulting from this situation it is the bounden duty of each of these groups of practitioners to seek counsel from one another, thus aiding in the conservation of the health of the public. The duty of each is plain. Let us do our part in eradicating the disparities.

It is asking more than we can expect that evils of this nature be obliterated in a day, but if these few words will aid in bringing about some little improvement in the relationship of dentist and physician, the aim of the writer will have been accomplished.

38 EAST SIXTY-FIRST STREET.

The Ultimate Cause of Most Apoplexies*

THOMAS F. REILLY, M.D.
New York

This presentation is the result of stumbling on a rather constant phenomenon found during the course of a close observation of the mouth and throat of every patient seen, both in hospitals and private practice, during the past four years.

The general finding of evidences of influenza, past or present, in so many mouths, at first did not attract our attention until we were able to connect up these with the other findings which at first seemed accidental; particularly was this so with vascular lesions in the brain. On examining the supposed accidental findings, it was found that the signs and symptoms of influenza were almost always present in a patient suffering from the brain lesions of apoplexy, so a connection seemed assured. A similar connection had previously been determined by the author with regard to the association of most of the attacks of cardiac decompensation and influenza. Of this cardioinfluenzal incidence there is not the slightest doubt in my mind, and I have seldom seen a cardiac breakdown that was not associated with slight rise in temperature, and the signs to be described later.

The cause of an apoplexy, in the last analysis being a vascular lesion, was logically only one further step. Why does the patient go to bed apparently quite well, and wake up paralyzed? The old idea that some added strain, as lifting a weight, thus inducing a rise in pressure, consequently causing the break in the vessel, is exploded. But why did the apoplectic attack occur last night and not one or two months ago?

The older pathology predicated that in the last analysis, vascular degeneration or disease was largely a progressive steadily advancing lesion. The present pathological conception of most degeneration and disease is that it is the result rather of a series of acute insults or diseases. But what is the disease that causes the last straw as it were? The usual pen picture that a stroke is due to increased arterial tension producing hemorrhage by the giving way of a bloodvessel, is quite useful to use as a figure of speech to convey to the mind of the layman what has happened in strokes, but it will scarcely satisfy the physician as to the mechanism of occurrence of the most common cause of hemiplegia, because, in the last analysis, most hemiplegic attacks are thrombotic rather than hemorrhagic.

THE EXPLANATION OF THE CROWNING ATTACK

In disease of any kind, one visualizes an outpouring into the blood of organisms of one sort or another. During the struggle between the disease and the individual, the blood is surcharged with organisms that are constantly being destroyed. It is quite a reasonable assumption, that finding a diseased vessel such organisms will lodge there, and that an already degenerated vessel has just such an affinity for them and particularly is there a chemotactic attraction for them in the lenticulostriate artery. One meets with a similar vascular phenomena in the association of influenza with external hemorrhoids, phlebitis, and ocular conjunctival hemorrhage occurring, as they so usually do, in the course of a head cold or influenza. Another occurrence of a somewhat similar phenomena occurs in the mycotic aneurysms so commonly present in cerebral hemorrhage.

As to why hemorrhage occurs in one group, and thrombosis in another, I have no data, but from some observations I believe it to be a family idiosyncrasy. Whether the primary cause of the faulty vessel is arteriosclerotic or luetic there is the same frequency of accompanying head colds. Of course the embolic phenomena due to a vegetative endocarditis, are quite easily understandable on a similar basis. This latter phenomena, excepting in the cases of bacterial endocarditis, is almost always associated with an influenzal syndrome in the throat.

There are many other interesting facts to be noted in this connection. If a similar phenomenon occurs about or in a bloodvessel, as it does in epidemic encephalitis (an influenzal disease), one can readily visualize an explanation of the mechanism of production of the temporary hemiplegias, and temporary aphasias that one occasionally meets with in the course of patients suffering from high arterial tension. In the last two instances of this transitory form of hemiplegia that we have seen, we have noted the evidences of the accompanying signs of influenza. In this connection I wish to reemphasize that the temperature should be taken by rectum, thus the supposed cold skin of the patient will be shown to be a cloak for a rise of one half to one degree of temperature. The shock of the stroke will often lower, for a few hours, this temperature which has already been present for a day or two, but towards the end of the same day it will generally mount to a degree or more.

The objector will at once raise the question, How do you know that these signs mean influenza? and, How do you know that they are related to the attack when the patient denies that he has influenza? In this matter several general statements may be made which are not commonly known, that influenza is a periodically recurring disease, occurring every thirty years or more in pandemic form, and several times annually, much like the seventeen year locusts, as compared with average annual locust crop; that once infected the individual probably remains a potential host for the disease as long as he lives; or else has been sensitized to the disease; that there is a recurrence of the disease in the shape of a head cold every sixteen weeks, perhaps oftener, and with more virulent symptoms every thirty-two or thirty-three weeks (except when the date occurs during the summer, when the virulent attacks are usually absent); that at times these thirty-three weeks recurrences are severe enough to attract attention.

As to differentiating between a socalled head cold and influenza, I know of no criteria. Everyone has seen a mild head cold in one member of the family, so mild that no attention is paid to it, and a few days

*Read before the Section of Neurology, general meeting of the New York Academy of Medicine, April 17, 1925.

later another member of the family comes down with a severe influenza and diet of it, or its sequelæ, and one is unable to differentiate the mouth and throat of one of these cases from that of the other one. After several such experiences one loses faith in the old time distinctions between cold and influenza and grippe.

The frequent recurrences of head cold will be noted by all of you if you will take the trouble to go over your histories and count up in any patient the incidences of head colds. The hemiplegic denies the head cold; so do most of your patients, but a thorough inspection of the mouth and throat will convince the most skeptical. One in this way will often acquire an uncanny reputation for predicting an influenza at its onset, when there are no signs or symptoms excepting those that occur in the mouth.

Again, why does the hemiplegic generally die of a bronchopneumonia on the third or fourth day? What evidence have we that merely brain injury of itself should produce infection and disease of the lung? The mode of death in these cases exactly simulates that which occurs in an ordinary influenza (bronchopneumonia). How will we determine the presence of head cold or socalled influenza and grippe? If one examines the patient very carefully and looks in the mouth and throat he will be surprised to find one or another, seldom more than three, of the following signs or symptoms: 1. A slight rise of temperature, one half to one degree by rectum, which rises ever so slightly for three and one half days, then to fall and rise again for a three and a half day period (this temperature must be taken by rectum. 2. A congested throat, pharynx and anterior arch of the soft palate. 3. The uvula will be injected, often containing red papules. 4. Farther up in the soft palate will be very minute puncture hemorrhages, and sagolike bodies. 5. On the side of the mouth Steno's duct (provided the man has back teeth) is enlarged, swollen, with a red spot in the middle. 6. Occasional hemorrhagic pin point areas throughout the mouth. 7. The lips are often crimson. 8. The external conjunctiva is injected. 9. Sometimes the fingernails are cyanosed.

Of all of these signs the injection of the anterior pillar of the fauces, with injection of the external margin of the ocular conjunctiva and increased temperature are the most constant.

The question at once will be asked as to why one has no postmortem studies on these cases. In the first place, there is no settled agreement as to what organism is the cause of influenza, consequently this would undoubtedly render any such approach valueless, and the presence of secondary invaders would further fog the diagnosis.

It is merely because of the relationship between the phenomena of endocarditis and phlebitis and influenza that we have a basis for this presentation. The percentage of positive signs in hemiplegics in the course of the four years' observation was practically ninety per cent., and that is quite as constant a percentage of positives as are Wassermann or Widal reactions.

As far as I have been able to ascertain, both from conversation with neurologists and the literature, I have been unable to find a similar association noted. I do not believe that this concurrence of influenza and of stroke is universal, as there is "no" or "never" or "yes" and "ever" in medicine, but the presentation does serve to hold out some possible hope in the future if it is proved that this connection is real, for the hemiplegic who is now not a therapeutic problem. When at his bedside our hands are literally and figuratively in our pockets, and little is to be done for him. It is fair to assume that eventually some sort of specific will be found for influenza.

I am not prepared to claim any specific value for local treatment to the mucous membranes, although such treatment would seem at least logical in attacking the focus of the infection. One hopes that the future will reveal some sort of vaccine or serum, but at present there is no general agreement as to the value of either.

34 West Eighty-eighth Street.

Eosinophilia in Scarlet Fever.—V. Markovitch and M. Gueratovitch (*Presse médicale,* February 14, 1925) find that the eosinophilic reaction in scarlet fever is governed by the clinical form of the disease. Thus, eosinophilia is pronounced and reaches its acme in the mild forms of scarlet fever unattended with complications. In severe forms with complications, the eosinophiles are low during the acute stage of the disease and of the complications; along with improvement in the general condition a rise in the eosinophilic curve takes place. In the hyperseptic forms, running a fatal course, the eosinophiles are absent or normal in number; the system is overwhelmed and fails to react. In incomplete [fruste] cases of scarlet fever, the eosinophiles constitute an important diagnostic feature, alike at the onset and in later stages of the disease. In scarlatinoid erythematous rashes, if the patient is in good general condition and the eosinophiles are normal, the thought of a possible scarlet fever may be dismissed.

Functional Mental Disorder Due to Toxemia from the Bowel.—James Walker (*Lancet,* November 22, 1924) reports three cases of functional mental disorder due to toxemia from the bowel in which deceptive signs of organic diseases existed, including a case of hypochondriasis, one of toxic psychosis simulating clinically general paralysis, and one of functional mental disorder resembling a case of organic nervous diseases, in which alimentary toxemia is an important causal factor.

The following deductions can be made from the study of these cases: 1. The nervous system is susceptible to the influence of toxemia either of exogenous or endogenous origin. 2. Toxemia of intestinal origin is more frequent than is generally accepted, its deleterious action being more easily produced and more marked when the general health is either reduced by previous illness or the powers of resistance impaired by such agencies as heredity, personal neglect and malnutrition, and unhealthy environment. 3. Provided the toxemia has not produced definite organic changes, it is quite safe to give a good prognosis. When recovery is complete an attempt should be made to explain to the patient how the illness was caused, in order to ensure a more satisfactory mode of living and at the same time considerably lessen the chances of recurrences.

Instruments, Apparatus, and Clinical Notes

A SIMPLE ASPIRATING APPARATUS

GEORGE G. ORNSTEIN, M.D.
New York

One who has used the Potain aspirating syringe is familiar with the inconvenience caused by the small pump which is a part of the apparatus. A good vacuum is only produced after considerable effort. When pus is encountered it is with difficulty that it is aspirated, and, at its best, is a slow process of emptying a pleural sac. If a good vacuum could be created the Potain apparatus would be an efficient one. A mechanically driven aspirator is out of the question because of the bulk and the expense of such a mechanism. A simple and inexpensive suction device which is not bulky and easily portable is what is desired. It occurred to me that a Chapman filter pump, which is easily attached to any smooth faucet by means of a rubber connection, would be the very thing for the formation of a strong enough vacuum to empty quickly a pleural sac of its fluid contents.

APPARATUS

A glass bottle of two thousand c. c. capacity, Fig. 1-C, is made air tight with a rubber stopper through which two tubes are inserted. One tube to extend about a half inch below the rubber stopper and the other about an inch. A stopcock is inserted in the latter tube, Fig. 1-A. Rubber tubing connects this tube with the aspirating trochar, Fig. 1-N. The other tube is connected with a Chapman filter pump, Fig. 1-F. Between the tube and filter pump is inserted another small bottle, Fig. 1-S, which is similarly made airtight by means of a rubber stopper and two tubes. A mercury manometer, Fig. 1-M, with a scale in inches is placed between the two bottles. The connection is made with a T tube, Fig. 1-T. The horizontal part of the tube is connected with both bottles and the vertical part of the tube is attached to the mercury manometer. A stopcock is inserted on the filter pump side of the T tube, Fig. 1-B.

Stopcock A is turned off. Stopcock B is turned on. The water faucet is turned on and the water is allowed to run until a vacuum is obtained. This is indicated by the mercury being drawn up on the bottle C side of the scale. Stopcock B is turned off. The trochar is thrust into the pleural cavity and stopcock A is turned on. The exudate now flows into bottle C. It has been our experience to note that each few hundred c. c. of fluid reduces the vacuum by an inch of mercury. This perhaps is the reason for the failure of most aspirating devices. As the fluid volume increases in the bottle the vacuum decreases until there is not enough suction present to continue the process of aspiration. This can be avoided by opening stopcock B and having the faucet turned on with enough pressure to maintain the desired vacuum. For the evacuation of pleural transudates one inch of mercury is required. For exudates two to three inches of mercury is necessary depending upon the specific gravity of the exudate. For pus to flow in a stream not less than eight inches of mercury pressure is required. The amount of mercury pressure may be kept constant by the adjustment of the flow of water through the faucet. Bottle S is inserted to prevent any water being aspirated into bottle C from the tubing leading to the filter pump. This frequently happened when stopcock B was turned on and the suction in bottle C was greater than in the tubing. This would contaminate the exudate or pus in the bottle and interfere with its examination. If one could always remember not to turn on stopcock B before the faucet is turned on, bottle S could be eliminated.

The adaptability of this apparatus cannot be questioned inasmuch as there is a faucet present in almost every house. However, when a faucet is not present in the house of the patient, the vacuum in the aspirating bottle may be made at the office and the apparatus detached from the filter pump. If there is not sufficient vacuum to drain all of the fluid in the sac before the end of the vacuum (this may be foreseen by the smallness of the stream) the bottle is placed at a lower level than the thorax and stopcock B opened. Drainage will now go on by siphonage.

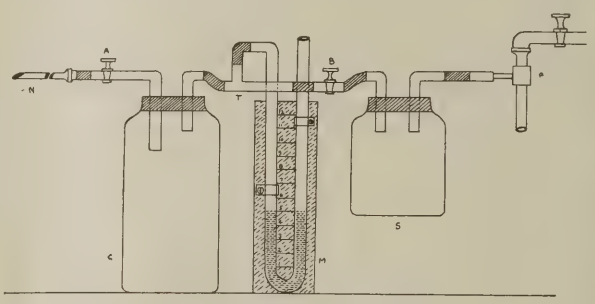

FIG.—Aspirating apparatus

It is best to have the apparatus attached to the filter pump. One can then control the withdrawal of the fluid with the pressure of the water going through the filter pump. The patient may be brought into the kitchen and placed on the kitchen table. However, should the patient be too ill to be moved, the following procedure may be carried out. A vacuum is made in the aspirating bottle. Stopcock B is turned off. The apparatus is detached from the filter pump and brought into the room of the patient. A needle is inserted into the pleural cavity and attached to the suction apparatus. Stopcock A is turned on and a stream of fluid flows from the pleural sac into the vacuum bottle. If the vacuum is not sufficient to completely drain the pleural sac the process of siphonage can be installed as described above. However, it is best to turn off stopcock A and place an artery clamp on the rubber tubing between stopcock A and the needle. Detach the apparatus from the needle and connect it again with the filter pump until a new vacuum is created. The apparatus is again attached to the needle and the process of aspirating the pleural sac is continued.

The apparatus has been tried out at the Metropolitan Hospital where I have a tuberculous service. It worked efficiently in simple pleural effusions and

in pyopneumothorax. It was possible with this apparatus not only to drain off the pus in a pyopneumothorax but also, by inserting into the upper part of the pleural sac another needle connected with a fountain syringe containing a weak solution of the tincture of iodine, to wash out the pleural sac. As rapidly as the fluid flowed into the sac the suction apparatus drained it out. This was continued until the fluid returned as clear as when it flowed in. This is a simple procedure of washing out a pleural cavity. I believe the same procedure could be applied to an empyema.

150 West Fifty-fifth Street.

A SIMPLE APPARATUS FOR BLOOD TRANSFUSIONS*

Henry M. Feinblatt, M.D.

Brooklyn

The following simple apparatus for the transfusion of blood by the vein to vein method was devised by me in order to reduce the difficulties of instrumental manipulation to a minimum and to obviate the possibility of a reflux of blood from the recipient to the donor. The machine consists essentially of two discs rotating one upon the other through an angle of 90°. The proximal disc is perforated to form a channel for communication with the syringe; this opening alternately becomes continuous with either of two similar openings in the peripheral disc, for the inlet and outlet respectively.

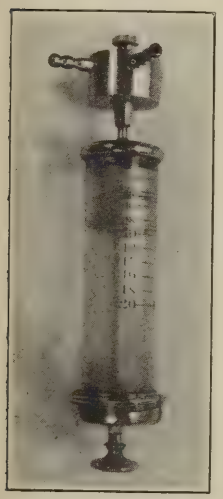

Fig. 1.—Transfusion apparatus attached to twenty c.c. record syringe.

EXPLANATION

Fig. 2A is an ordinary twenty c. c. record syringe, the tip of which fits into the proximal disc of the instrument. This connection may be locked by means of a bayonet catch. Each of the two discs is made of brass, heavily nickeled, and measures one inch in diameter by five sixteenth of an inch in thickness. On its proximal surface the proximal disc B is continued into a metal tube a, for the reception of the tip of the syringe; on its distal surface it is continued into a shaft, b, for insertion into the distal disc, thus allowing rotation of the discs one upon the other. The portion of the shaft which projects beyond the distal disc is threaded for the reception of the nut, D. Midway between the centre and the circumference the distal surface of the proximal disc is perforated by an opening for communication with the syringe. A small pin on the circumferential surface of this disc provides for the correct angle of rotation, 90°, limiting further movement as it strikes against the projecting arms of the stop regulator h; a marking, c, on this surface shows whether the syringe is connected with the outlet or the inlet.

The distal disc is perforated in the centre for the reception of the shaft of the other disc. Midway between the centre and the circumference, the proximal surface contains two openings, d and e, similar to the single foramen in the other disc; they are separated by an angle of 90° and become continuous

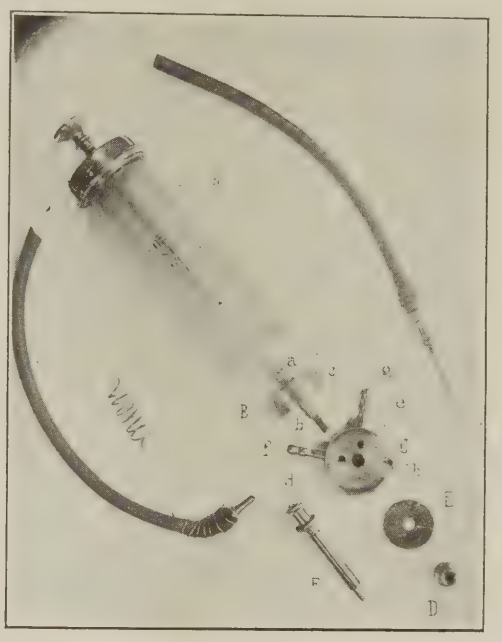

Fig. 2.—A, twenty c.c. record syringes. B, proximal disc; a, metal tube; b, shaft threaded at the extremity; c, marking showing whether communication is with inlet or outlet. C, distal disc; d and e, openings communicating with inlet and outlet tubes respectively; f and g, each of which alternately comes into apposition with the single opening in the proximal disc, as the discs are rotated; h, stop regulator with two projecting arms. D, nut. E, steel spring washer. F, needle for use in infants.

with the metal outlet and inlet tubes, f and g, respectively. A stop regulator, h, with two projecting arms to limit the range of motion to 90°, is screwed onto the circumferential surface of this disc. Between the nut and the distal disc there is interposed a steel spring washer, E.

A piece of rubber tubing with an adapter is attached to the inlet and the outlet respectively. A wrapping of wire at the point of junction with the adapter serves the useful purpose of keeping the end of the tube bent in any position desired. The type of needle illustrated in Fig. 2F has been found convenient for use in infants. I prefer to use needles without the flange, as the weight of the latter is likely to pull the needle out of the vein during the procedure.

The machine, with the inlet and outlet projecting upward, may be held in a slotted holder, which is clamped onto the table. At the start of the operation the syringe contains normal saline solution, which is slowly injected into the vein of the recipient. In the meantime the vein of the donor has been entered. All that is necessary to transfer the communication with the syringe from the donor to the recipient, or vice versa, is to rotate the discs one upon the other.

This apparatus has been successfully employed in 220 transfusions and, for ease of manipulation, has proved superior to any other instrument which the writer has used.

I am indebted to Mr. F. J. Billings for valuable help in the mechanical perfection of this instrument.

616 Carleton Avenue.

*From the United Israel Zion Hospital, Brooklyn.

Wax Models in Teaching Surgery.—F. P. Johnson (*Surgery, Gynecology and Obstetrics,* May, 1924) describes the preparation of wax models as follows: The portion of the surface of the body to be modelled is shaved and coated with a thin film of mineral oil. A thick layer of dental plaster of Paris, properly mixed with water, is then carefully spread over the part. The plaster is allowed to harden and the mold, a negative, is lifted off. After the mold has been allowed to dry at room temperature for two or three days, it is then soaked in cold water until it is thoroughly saturated. Any excess water is sponged from the surface with absorbent cotton and the mold is immediately filled with melted wax. He gives photographs of the different stages of an operation in which this method was employed and concludes: The teaching value of the models herein described has already been demonstrated. They lend themselves equally well to individual or group teaching. They give to the student a better idea of the operation than he could obtain in the operating room for at his leisure he can study all details without missing a single step. Not only is modelling of value in surgery from the viewpoint of showing operations, but the method can be used for other purposes as well. Tumors, ulcers and malformations, if they present themselves externally, are simple to reproduce in wax. The method is excellent for recording the results in plastic surgery, for impressions can be taken before and after the several stages of operations of this kind. It was in this connection that the author became interested in modelling. A number of cases of hypospadias and other malformations of the external genitalia were modelled before and after operation and thus accurate records of the results obtained are made available.

Repeated Blood Transfusions in Progressive Pernicious Anemia.—Emile-Weil, Isch-Wall, Pollet and Lamy (*Bulletins et mémoires de la Société. médicale des hôpitaux de Paris,* January 29, 1925) report twelve cases of grave cryptogenetic pernicious anemia treated by repeated transfusions of 300 c. c. of blood, at first weekly, then fortnightly, and finally monthly. The total number of transfusions ranged from two to twenty-eight. Repetition of the procedure was based on blood examinations, another transfusion being carried out when the red cells and hemoglobin failed to rise any further or sagged. Transfusion seems capable of transforming a hypoplastic anemia to one of the plastic type, at least for a varying period, without any attendant modification of the prognosis, a sharp plastic reaction being sometimes only temporary. The prognosis must depend on the clinical course rather than on any single plastic reaction, however pronounced. In two out of the twelve cases the red cells and hemoglobin returned to normal after three and five transfusions, respectively, and were still normal two and three years later, in spite of an active, fatiguing mode of life. Seven patients were afforded a remission more pronounced and lasting than any other treatment would have given. In four other cases improvement was maintained only for a few weeks, but in these the condition appeared to have been one of cancerous disease of the digestive tract with pernicious anemia, though no autopsy was allowed. The efficacy of the transfusion treatment is shown in that in several instances it proved active in hemolytic relapses, against which no useful measure had previously been found. To obtain more perfect results it would be necessary to know how to overcome the digestive disturbances which are probably responsible for the hemolysis. At all events, transfusion betters the course of pernicious anemia as much as does digitalis that of heart affections. Its efficacy varies, as does that of digitalis, according to the reactive power of the structure concerned, in this case the hematopoietic organs.

Clinical Hemoglobin Estimation.—Richard A. Kern (*Medical Clinics of North America,* November, 1924) finds that the Sahli type of hemoglobinometer is best adapted for routine hemoglobin estimations, because it is simple, easy to use, inexpensive, accurate to five per cent., and serviceable both in daylight and artificial light, while its standard is reasonably durable, can readily be checked as to its accuracy, and can be made satisfactorily in the average hospital laboratory. Hemoglobin estimation by this method should be a part of all routine clinical blood examinations. The practitioner should consider the method as one of the most valuable of clinical procedures at his command. Hemoglobinometers should be graduated in absolute values of grams of hemoglobin per 100 c.c. of blood as well as in per cent. of an assumed normal: 15.6 grams of hemoglobin per 100 c.c. of blood with a count of 5,000,000 erythrocytes (20.9 volumes per cent. oxygen capacity) is endorsed as a figure to represent "100 per cent. normal" for practical hemoglobinometry.

The Van Slyke oxygen capacity method for the estimation should be used in every clinic because it combines great accuracy with ready availability and the simplest technic of the really accurate hemoglobin methods. It should find its chief application in the calibration and preparation of proper standards for clinical colorimeters. An occasional oxygen determination in cases of severe anemia or polycythemia will be valuable both in diagnosis and as a check on routine hemoglobin estimations.

The Paul Test in the Diagnosis of Smallpox.—Charles E. Simon and Joseph M. Scott (*Journal of Laboratory and Clinical Medicine,* April, 1925) present this communication to emphasize a conclusion that they published a year ago, namely, that, histologically controlled, the Paul method in the diagnosis of smallpox is reliable and deserves general application in all doubtful cases. The technic of the method is described. In forty-four of the forty-five cases of bona fide smallpox the macroscopic picture of the inoculated rabbit cornea in the sublimate alcohol bath was in itself sufficient to reach a diagnosis. In the one doubtful case, as in the thirty-nine others in which sections were examined, the histologic picture was a clearcut positive one for smallpox. In none of the cases of varicella or the other skin diseases examined was a reaction noted that even remotely suggested a positive one. The smallpox virus was found in one instance to retain its activity in the dried drop preparation, at icebox temperature, for 387 days. Before release from quarantine, a careful rhinoscopic examination should be made in all smallpox cases, and followed, if considered necessary, by the application of the Paul test to the nasopharyngeal secretions.

Tuberculosis of the Hip in Children

HERBERT E. COE, M.D.
Seattle, Wash.

Tuberculosis of the hip may be defined as a tuberculous infection of one or more of the structures composing or immediately contiguous to the hip joint.

ETIOLOGY

This condition may occur at any age, but about eighty per cent. of all cases are in children, and this paper is restricted to a consideration of these cases.

Sex has practically no bearing, as the characteristics, environment and activities of the two sexes during childhood are so similar. Climate is a distinct factor, because it may be generally stated that any condition as, for example, inclement weather, which tends to restrict out of door activities and to favor the assembling of persons in places which are frequently overheated and poorly ventilated, diminishes exercise, impairs the appetite, and interferes with elimination, thus lowering the general resistance; and any such condition also favors the development and spread of respiratory infections. This disease is always the result of infection and is always secondary, although the portal of entry may have healed completely, long before the manifestations in the hip appear. The gastrointestinal and the respiratory tracts are the two avenues by which the tubercle bacillus gains entrance in the vast majority of cases, and these indicate the two main sources of infection—food and air borne particles.

The effect of trauma is rather difficult to determine, for a history of frequent falls can be obtained from practically all children. The fact, however, that by far the greatest amount of joint tuberculosis occurs in the spine and lower extremities would seem to indicate that weight bearing and the effect of repeated jarring and bruising may be determining factors in the location of these secondary foci of infection.

ANATOMY

The normal hip is a ball and socket joint, beautifully and effectively contrived to withstand shocks, support the weight of the body in a great variety of positions, and still permit of a wide range of motion. The axis of the neck is at an angle of about 130° with that of the shaft, thus obtaining all of the mechanical advantages of an angular lever, but the mechanical weakness of angles is avoided by a wonderfully combined system of curves. The neck forms an even curve with the shaft, the head, neck and shaft are all roughly cylindrical, and the arrangement of the trabeculæ in the head and neck is in a series of long curves approximately perpendicular to the surfaces at the points of greatest pressure and passing inward and downward in such a manner as to prevent absolute rigidity and still provide great elasticity and dispersion of the forces of concussion and weight bearing. The fossa of the acetabulum has its greatest strength in the upper posterior portion in the direction of the greatest pressure, the lower portion being thin. The surrounding muscles pass from various points of origin on the pelvis to the greater and lesser trochanters, all being inserted well beyond the head.

PATHOLOGY

In nearly seventy-five per cent. of cases the head is involved first. The infection is usually hematogenous, the process gaining foothold near the epiphyseal line where the primitive function of cell reproduction is active and the secondary function of resistance is low. In a much smaller percentage of cases the acetabulum is first to suffer. As the involvement of the head progresses, trabeculæ are destroyed, undermining the supporting structure and interfering with the growth of the bone. The force of gravity and the constant tension of the muscles crush the weakened trabeculæ into the focus and the destruction increases.

These pathological activities about the joint have a reflex effect upon the nutrition of the leg and a more marked atrophy takes place than can be explained by interrupted function. As the process approaches the joint surfaces, nerves are involved, motion and slight jars are painful and muscular spasm develops in an unconscious attempt to limit motion. This effort, however, causes increased and continuous pressure upon the weakened bony structures resulting in more rapid destruction and the

formation of a vicious circle. If suppuration takes place the abscess may perforate the periarticular structures and appear beneath the skin, or it may invade the joint cavity, perhaps appearing later externally or even eroding the thin floor of the acetabulum and penetrating the pelvis.

Where the acetabulum is involved early the constant effect of weight bearing and the crowding of the head against the upper rim by the tension of the muscles causes erosion of the rim and the head gradually migrates upward until a complete dislocation may occur. Sooner or later pain and muscle spasm cause a fixation of the joint and ankylosis takes place—generally in a position of adduction and flexion. This is the usual termination in untreated cases and it occurs when resistance has developed and when motion of the opposed, irritated, bony surfaces has ceased for a sufficient period to permit osteogenesis.

SYMPTOMS AND SIGNS

Bearing in mind these points of pathology, the more usual symptoms are easily remembered. Briefly, they are limp, muscle spasm, pain, attitude, atrophy and swelling.

The limp is usually the first thing to attract attention; frequently it is intermittent and without pain, often like a slight stiffness just after rising in the morning, soon wearing off and frequently not noticed again during the day.

Muscle spasm is first seen in a tendency to guard the joint against jars, by walking on the toes and by avoiding running; also, there is a tendency to avoid pressure by standing on the other foot with the affected leg everted and slightly abducted. There may at first be apparent lengthening of the affected leg due to this abduction and the consequent tilting of the pelvis toward that side. As the disease progresses the muscle spasm increases, finally becoming so marked and constant that motion of the joint is greatly restricted. This spasm is one of the most important signs of the disease, not only on account of its diagnostic importance, but also as an index of the efficiency of treatment, and its reflex character increases its value.

Pain is not usually a marked symptom early in the course, although occasionally severe. It is most commonly referred to the lower part of the thigh on the inner side just above the knee. This location depends upon the anastomoses of the sciatic, obturator and anterior crural nerves, and it is so constant and characteristic that unilateral pain in the knee of a child should always be considered serious until proved otherwise. Pain is also the cause of the characteristic "night cries" which are often noted. They usually occur in the early part of the night just after the child has gone to sleep. This "night cry" is a sharp cry of sudden, severe pain although frequently the child does not actually waken, and it is due to the abnormal irritability of the muscles. The muscles relax slightly as unconsciousness deepens until a slight motion or fibrillary twitch throws them suddenly into a state of strong contraction driving the head of the bone forcibly into the acetabulum. One can easily imagine the resulting pain and older persons who have experienced it compare it to a heavy blow upon the hip. The pain leaves almost immediately, due to the fixation of the hip by the spasmodic contraction, and this explains the fact that the child frequently does not waken completely.

The attitude of the affected leg is quite noticeable. In the early acute stage it is held in a gradually increasing degree of flexion, abduction, and external rotation. After the continuance of muscle spasm for some time the greater leverage of the adductors finally overcomes the resistance of the opposing muscles and results in a position of flexion and adduction. The extreme to which this contraction may go is illustrated by the case of a little patient with double tuberculous hip disease who had been treated by an osteopath for rheumatism until the torture of the frequent manipulations compelled the parents to drop the treatment, and when seen shortly afterward both thighs were held by muscle spasm rigidly crossed over the abdomen.

Atrophy of the affected leg is early and marked, usually being distinctly noticeable before the period of disability begins.

Swelling can be detected early by deep palpation over the head of the femur from the front and is due to the inflammatory reaction in the periarticular tissues. It is also frequently perceptible from the back, often being of sufficient amount to cause a change in the gluteal folds which can be noted on inspection. When the thickening is on the lower, inner side of the joint the cleft of the buttocks or vulva can be seen to be displaced slightly to the opposite side.

DIAGNOSIS

The early case of tuberculous hip is usually brought to the doctor on account of a limp. The parent states that several times during the past two or three months the child has limped for three or four days without any apparent cause. Sometimes the limp has worn off during the morning, sometimes has been noticed to reappear once or twice during the day; there may have been no pain at all or there may have been a slight lameness of the knee at times. The history may be otherwise entirely negative, or inquiry may show a possible tonsillar or glandular infection some time previously. Pulse and temperature may be normal, especially if taken in the interval between periods of limping, and the general appearance may be that of a vigorous, healthy, well nourished child. If the child be stripped and laid upon the table there will nearly always be found a slight thickening over the head of the femur as compared to the normal side, and when the thigh is flexed at a right angle to the plane of the table and then laid out to the side the motion will be stopped distinctly sooner on the affected side than on the normal, due to the contraction of the adductor muscles. Also gentle rotation with the thigh raised to a right angle will be found to be more or less limited. If it is desired to test extension the child is turned on the face and each leg raised in turn and it will be found that the affected one draws the pelvis up much sooner than the normal one. In an early case this is frequently all that can be found on physical

examination. At this stage also a slight atrophy may be found upon careful measurement. Jarring the joint by striking the heel or trochanter is rarely necessary for diagnosis and should not be routine, as the avoidance of unnecessary pain is fundamental in the examination of children.

The x ray in these early cases is often absolutely normal, the process not having progressed far enough to show increased radiability of the bone, and the occasionally seen periarticular cloudiness is so slight as to be of no diagnostic value. The blood count is usually well within normal limits; a Von Pirquet test in children under four years of age is of value, and a negative test in older children is a good indication that the condition is nontuberculous.

In more advanced cases the history of limp and of pain in the knee is more definite, to which is often added the history of "night cries," general malaise, loss of appetite, occasional fever, loss of color, and stationary or falling weight. In such cases the characteristic attitudes of standing, walking or lying may be seen; the pulse rate is usually increased, and there is an afternoon elevation of temperature. Physical examination will show distinct periarticular thickening and occasionally pain on pressure over the joint, atrophy, marked limitation of motion with adductor spasm, and the changed gluteal fold already mentioned. At this stage also the x ray is usually of diagnostic value.

TREATMENT

The object of treatment is twofold; first, the development of a local and general resistance sufficient to prevent the extension of and finally heal the local process, and second, to restore as nearly as possible the normal function of the joint. Anything which improves the general resistance will, of course, improve the local, and so all the general measures which apply to tuberculosis in any location are indicated—improved nutrition, fresh air, removal of local sources of infection, heliotherapy, etc. Theoretically the use of tuberculin would seem indicated when the specific resistance does not improve under general measures and the tuberculous infection is not overwhelming, but in a case in which the local condition is not advancing and the general resistance is good it seems logical to assume that the body is well supplied with specific antibodies and that the stimulation of further antibody production is not indicated; also, until we are more familiar with the phenomenon of anaphylaxis we would do well to refrain from the introduction of an antigen which may interact with the antibodies already present and produce the undesirable effect of hypersensitization.

The complication of abscess formation is to be treated as occasion demands, the general principle being to avoid secondary infection whenever possible, and this means incision only when general and local measures, such as feeding, hygiene, local heat, and aspiration are unavailing. When sinus formation has occurred the course is usually protracted and here again the improvement of the general condition is one of the greatest factors in a successful result; locally, unobstructed drainage is the first essential and this may be supplemented by local applications or injections of various kinds, by hyperemia induced either by the method of Bier, by hypertonic solutions, by heliotherapy or other forms of radiation, or by dry heat; also, perhaps, the use of vaccines in selected cases to combat secondary infection.

The operative procedure of extensive removal of diseased bone, often including large portions of the head or ilium, should be reserved for the most advanced cases and used only when a thorough trial of other methods has failed to produce results, for if the tuberculous process can be overcome by improving general and local resistance, bone regeneration may occur, replacing to a variable extent the former infected area. If, however, portions of the joint have been removed, there is no framework remaining for advancing osteoblasts to follow; there is always destruction of periosteum and synovial cartilage; and there is nearly always apposition of raw bony surfaces which results in ankylosis.

The second object of treatment, the prevention of deformity and restoration of function, requires early and persistent attention. From a review of the pathology we see that the first essential is the prevention of the crushing of the diseased tissues by weight bearing and by muscle spasm. This requires rest in bed with sufficient traction to overcome the pull of the muscles. It also requires that the traction be in the direction in which the muscle spasm is least active, that is, in the line of deformity, whether this be toward the foot of the bed or over the shoulder, as otherwise the tense muscles act as a fulcrum forcing the short end of the lever against the acetabulum. Under this treatment the spasm decreases rapidly, pain and "night cries" cease, and the general condition improves. When spasm is absent the direction of the traction is changed slightly toward the normal, and this is continued at intervals of several days until the leg is straight beside the other, always waiting between changes of direction until both adductor and flexor spasm have completely disappeared, whether this be days or weeks.

After a period of one or two months in the normal position to permit of continued healing, the patient is ready for a splint and the one which seems to be most satisfactory in every way is the Bradford traction abduction splint. This consists of a ring which rests against the perineum, the ischial tuberosity and the outside of the hip above the trochanter, with a short projection which holds the leg in slight abduction. To this ring are attached two rods which terminate well below the foot and carry a small racheted bar to which may be attached the straps of an ordinary Buck's extension which may be adjusted, by turning the bar, to any desired degree of traction. The object of such a splint is to enable the child to become ambulatory at the earliest possible time and thus employ the powerful influence of general muscular activity in the development of health and resistance. Such a splint maintains traction relieving the diseased surfaces of pressure; immobilization, although not absolute, is sufficient for healing; ankylosis is prevented in most cases, and the resulting function is usually excellent.

The value of this ambulatory treatment is so great that the Massachusetts Hospital School, which has a series of several hundred cases, has made it routine, condemning and discarding completely the former

method of treatment by plaster without extension. The duration of the bed treatment is determined by the extent of the process at the beginning of treatment, as it must be continued until the local disease is quiescent, the spasm is absent, and the leg is in as nearly normal a position as possible. This is seldom less than three months and may be as long as eighteen months. The duration of ambulatory treatment is usually from two to three years, the splint being removed at night during the latter five or six months of this time. The utmost care in changing the extension is necessary during the earlier part of the treatment, for traction must be maintained constantly lest the head be allowed to come against the acetabulum with sufficient force to cause reflex muscle spasm and thus delay healing or even destroy the delicate, newly formed cells.

This last point shows clearly the serious fallacy of the plaster cast treatment, for no cast ever applied can fit the leg so closely as to maintain traction on the hip joint. The interior diameter of a cast increases as the plaster dries, the tissues atrophy both from the disease and from disuse, and muscle spasm continues to pound the diseased acetabulum with the diseased head. A more effective method for the production of ankylosis could scarcely be devised. In addition, the cast is at best heavy and cumbersome, interferes with activity, and often the only modification which it makes in the end result is that ankylosis may take place with less deformity than when the case is left to go untreated.

There are undoubtedly cases in which fair results have been obtained with the cast method of treatment, but the course of these cases is always longer than is necessary and it is doubtful whether the end results are ever as good as possible. A review of the cases treated at the Children's Orthopedic Hospital in Seattle under both the previous and present methods bears out the experience of the Massachusetts Hospital School. Under the plaster treatment the records usually show frequent periods of extension in bed following acute exacerbations which have occurred after wearing plaster for varying periods of time, and usually a final condition of ankylosis in a more or less abnormal position; while under the present treatment the period of disability is much less, exacerbations have not occurred, and the present function in most cases is excellent.

PROGNOSIS

The prognosis of tuberculous disease of the hip when efficient treatment is begun early is excellent. Deformity is always limited and often entirely prevented, the period of disability is not great, and is modified by the ambulatory splint so that a child is able to attend school and continue many of the activities of normal life. In cases where treatment is begun later in the disease all variations of final result are seen, from the limitation of motion with slight shortening, up to complete ankylosis at a right angle with total destruction of the hip joint and inability to walk. In cases with marked deformity much can be done by osteotomy, physiotherapy and apparatus to make the condition more endurable, and in some instances such patients can be so improved as to become useful members of society. Cases with abscesses and sinuses always have a worse prognosis than others, for there is, frequently, absorption with resulting nephritis or amyloid degenerations and often secondary tuberculous processes in the lungs or brain, tuberculous meningitis being a sequela more frequently observed in tuberculosis of the hip than in that of any other joints.

Pyloric Obstruction in Infants with a Nervous Heredity

Report of Ten Cases

ROBERT L. PITFIELD, M.D.
Philadelphia

Very little is known about the etiology of pyloric stenosis in infants. Some ascribe the condition to hyperadrenalism, but this seems to have a merely conjectural basis rather than a positive proved one. It is, however, suggestive.

In the ten cases reported in this communication all the children were born of parents of whom one was decidedly neurotic. I believe that this neuropathic taint in one parent, inherited by the sick child, is manifested in early infancy by pylorospasm or organic stenosis. Freer in his excellent textbook states that pyloric disease in infants is a neurosis dependent upon a neuropathic ancestry.

Case I.—Baby G, a boy, was born prematurely, as were his sister and brother. His father was a stolid man, of excellent athletic physique, and not at all nervous; his mother was intensely neurotic and so was his sister. From birth it was necessary to nourish him artificially. During the first week he exhibited marked signs of thymus disease, which I failed to recognize as such until five months later. He became deeply cyanotic when his foreskin was stretched and in his bath. During my absence an officious nurse raised his formula so that it contained an inordinate and improper amount of fat. He was taking under this woman's feeding a formula containing seven per cent. fat, six per cent. sugar and one and a half per cent. proteid. Soon after this he began to vomit, retaining little of his food; his food was projected violently. He lost weight rapidly, exhibited active peristalsis in the epigastrium, and a small pyloric tumor was demonstrable in the right upper quadrant of the abdomen. A posterior gastroenterostomy was rapidly performed by Dr. J. B. Deaver (this was ten years ago), from which the child recovered satisfactorily. He gained weight

slowly and when five months of age the thymus began to obstruct his breathing, and catarrhal pneumonia supervened. Breathing became very rapid and the case seemed desperate. Vigorous x ray treatments reduced the dyspnea in a striking manner; he was given many treatments and recovered from the thymic disease.

Case II.—Baby P., a girl, at five weeks exhibited projectile vomiting. Obstruction of the pylorus being suspected she was at once examined by x ray, and an obstruction was easily demonstrated. There was retention of the opaque meal for over six hours, and a small pyloric mass was discovered. After waiting a week on account of the child having a cold, an operation was performed successfully by Dr. Harry Deaver. The child made a slow but satisfactory recovery. This infant's father is a superbly built man, an old college athlete and soldier. He is not nervous, and in every way is vigorous and strong. The mother is essentially neurotic. Once she exhibited such mental depression that she talked of suicide, and at another time was so nervously depressed that a prolonged rest cure was needed in order to restore her nervous tone. The child is now over three years of age and is not nervous.

Case III.—Baby T. S., when six weeks of age, exhibited projectile vomiting; he was partly breast-fed. On examination a pyloric mass could be easily felt and the characteristic peristaltic waves could be elicited on stroking the epigastrium. The child's mother was essentially neurotic, suffered from a neurogenic asthma and exhibited marked mental signs of a neurotic nature. Her mother in turn was even more neurotic than the mother of the child, and suffered from delusions of persecution and presented other evidences of a psychosis. The father was a finely built athlete.

A Rammstedt operation was quickly and skillfully done by Dr. Charles Mitchell, and the boy recovered after a slow convalescence.

Case IV.—B. S., a sister of the patient in Case III, when a week old exhibited some cyanosis and vomited all her food. A pylorospasm was suspected. Peristaltic waves were elicited in the usual manner in the epigastrium, but no mass could be palpated in the epigastric region. Because of the cyanosis, strychnine 1/1000th grain was given every three hours, together with massive doses of atropine 1/250th grain every three hours for twelve hours. Under this active and heroic treatment the child recovered and never again exhibited obstructive symptoms of the pylorus, and showed no signs of atropine poisoning.

Case V.—Baby L., a girl, at six weeks of age exhibited signs of pyloric obstruction. She vomited forcibly, the ejected food being thrown two and a half feet while the child was in the prone position. No pyloric mass could be felt. Faint epigastric waves were elicited on stroking the epigastrium, and the x rays revealed a five hour retention of food. Some of the opaque meal had passed into the duodenum; much was retained in the stomach at the end of this period. A huge thymus, suspected because of the pyloric condition, was easily demonstrated by the x rays.

The mother of this girl was a stolid woman, not at all nervous. The father, on the other hand, was not only neurotic, but was in an advanced stage of diabetes, requiring while on a maintenance diet eighty-five units of insulin daily to keep his sugar level below 300 mgs. to the 100 c.c. of blood. Once before marriage he had suffered from a mental breakdown lasting a year. Under thick feedings and atropine in doses of 1/500th of a grain with each bottle the child soon stopped vomiting excessively and gained weight satisfactorily. A skimmed milk mixture in addition to the farina mixture were necessary to control the vomiting.

Case VI.—A boy, aged one month, bottle fed, was admitted to the wards of the hospital, with the usual history of vomiting all kinds of food. The mother was a stolid English woman, and the father was neurotic, of an inferior constitutional build, having many stigmata, dilated pupils, and an anxiety neurosis. The boy was feeble, dehydrated, and emaciated, weighing only six pounds. A buttonlike mass was easily located in the epigastric region deep down, near the spine. No peristaltic waves were elicited on stroking the skin of the epigastrium, but upon palpating the pyloric tumor intensely deep waves immediately appeared, dividing the stomach into two balloonlike halves. Repeated palpations by several physicians produced such a spasm of the stomach that the child went into a semicollapse. Thick feedings were at once begun, atropine was given, also bromides, and because of the dehydration two intraperitoneal injections of normal salt solution with five per cent. glucose were administered, 200 c.c. each. No x ray examination was attempted. The diagnosis was patent to all. In two days a speedy and successful Rammstedt operation was done by Dr. Harry Knox. Subsequently another intraperitoneal injection was given because of dehydration. Thick feedings, alternating with a skim milk lactose mixture, were given, and after a period in which he did not gain, the child slowly recovered. When admitted he had a leucocytosis of 15,000 and a continuous fever, possibly the mooted inanition fever.

The following cases were reported to me by Dr. Radcliffe Cheston, who treated all four of them:

Case VII.—Baby X., a boy, shortly after birth exhibited signs of pyloric obstruction with projectile vomiting and small stools. A mass was found. Operation was successfully performed and recovery ensued, atropine and thick feedings having been employed. The mother was very nervous, the father healthy in every way.

Case VIII.—A boy at three months exhibited obstructive signs. Thick feedings were administered and atropine given. After a long siege of many months the child recovered. The mother of this boy was highly neurotic, but the father was not nervous and was healthy. The child was also neurotic, but is improving in this respect.

Case IX.—The patient, a boy, was operated on at five weeks, the diagnosis being confirmed at operation. The mother was not nervous, but the father was neurotic, this nervous condition no doubt having been aggravated by confinement in a German prison during the war.

Case X.—This patient, a boy, was operated upon at eight weeks by Dr. Francis Allen. A hypertrophied pylorus was found and split after the manner of Rammstedt, and the child recovered. The father of the boy was healthy in every way; the mother, as in most of the other cases reported, was highly neurotic.

Dr. K. reported to me the history of his own son, who was operated on by Dr. Harry Deaver, the diagnosis of pyloric obstruction having been made early by the father. The child recovered. The parents of this child were not nervous. The father was very intelligent and athletic in build.

In this series of ten cases, all of the children were of neurotic parents—three with neurotic fathers and seven with neurotic mothers. I have observed in this small group of cases that the combination of an athletic father and a neurotic mother was present in at least four families with a history of pyloric obstruction (five children). Athleticism is a form of hyperadrenalism, according to some writers.

There seems to have been a neurosis in ten instances at least, expressing an hereditary nervous imbalance in the children. This seems significant.

Constipation in Infancy and Childhood*

HARRY S. SNYDERMAN, M.D.
Philadelphia, Pa.

Constipation is very common in infants during the breast or bottle feeding period; indeed, it is so frequent that one would be led to suppose that some special cause peculiar to this age exists. It might be suggested that this cause lies in the fact that the diet at this time, being liquid, leaves little solid residue to stimulate the intestines to active peristalsis. However, this can hardly explain it entirely, for in the bottle baby fed on cow's milk, which has a large tough curd, one would suppose constipation to be less frequent than where the infant receives human milk which has a fine flaky curd. As a matter of fact the reverse is the case.

ETIOLOGY OF CONSTIPATION

The feeble musculature of the bowel has been held responsible for the frequency of this trouble in infancy, a view which gains support from the fact that feeble and premature infants are more prone to constipation than normal ones. Consequently, this lack of muscular strength in the bowel must be reckoned with as an important factor, but other causes must be considered as well, as sometimes the feeblest infants have regular bowel movements while a strong baby similarly fed may suffer from constipation.

The possibility that anatomical peculiarities may account for this tendency to constipation is suggested by observations on the relative lengths of the large intestines and the body, as they are compared at different ages.

The function of the large intestines is chiefly to absorb the liquid part of the food. Nature has provided for infants a food capable of rapid assimilation, and to secure abundant absorption special provision is made of a relatively large colon. At birth the large intestine is relatively much longer than the body. At the end of the second year it is several inches longer than the body. After the second year the difference becomes less marked, and as the child reaches four or five years the relationship is reversed. The large intestine becomes shorter than the body and in later years this relative shortness is even more marked.

From these observations it might be expected, owing to its relatively excessive length, some folding and kinking of this part of the bowels must be present in infancy. These folds and kinks will be more or less straightened out in later childhood by the enlargement of the abdominal cavity.

There can be little doubt that the sharp turns upon itself which the colon of an infant often makes in the sigmoid region must offer considerable obstruction to the course of the feces. The presence of feces must still further accentuate the kinking. In addition there is usually associated with these obstacles excessive feebleness of the muscle fibres. It is therefore easy to understand why an infant is prone to chronic constipation. These observations seem to explain the clinical fact that the constipation tends to right itself as the child grows older. The kinks and folds are diminished, as the colon is straightened out by the rapid growth in the length of the abdomen, and thus it may be truly said that the child grows out of the constipation habit.

I have dwelt on these causes of constipation in infancy somewhat fully because, even though they afford little guidance in treatment, they at any rate provide a reasonable hypothesis which explains the difficulty so often met in overcoming the condition at this age; and they give good ground for assuring the parents that there is every probability that the trouble will disappear as the child grows older.

Both in infancy and early childhood and even to some extent in older children there is a negative factor which may play an important part in the production of chronic constipation—I mean the absence of voluntary effort to cultivate regularity. The child, conscious only of a weak desire to defecate and of a much stronger desire to play, neglects the former in favor of the latter; and what is a wilful neglect at the time very soon becomes real inability.

It is customary to attribute constipation to fissure

*Read before the Southeastern Branch of the Philadelphia County Medical Society, May 5, 1925.

of the anus, polyps and to other local abnormalities. Undoubtedly these conditions may be operative as causative factors, especially on account of the pain induced by the passage of the fecal mass. This causes repression of the desire to go to stool. However, I believe that these conditions occur rather more often as the result of constipation than as the cause of it, and any successful treatment, therefore, must be directed toward the cure, not only of the fissure, or other condition, but, more important, toward the cure of the constipation.

Errors of diet and insufficient food, where there is very little residue or where food of an inappropriate composition as in the artificially fed infant is taken, must be considered and corrected.

RESULTS OF CONSTIPATION

Foremost among the evils of constipation in infancy I shall put failure to gain weight, or slow progress in nutrition. I have often seen babies placed on all sorts and varieties of food because of stationary or loss in weight, without improvement, when the real cause was constipation. Correction of the latter without change of food I have often seen followed by a gain. Another result of constipation is vomiting. I do not mean severe vomiting, but where the infant brings up half an ounce or more after each feeding. An infant who is said to be always screaming is very often suffering from constipation. The bowel makes vigorous but ineffectual efforts, and the result is colicky pain.

Convulsions, prolapse of the rectum, hernia, bloody stools, piles, which I have seen in an infant five and one half months old, anemia, various skin lesions, eczema, and toxic rashes, may be traced directly to constipation. In older children the anemia and failure to gain are common consequences. The child is pale, has a pasty complexion, is languid and tires easily on exertion, and suffers from headaches. The appetite is poor, breath is offensive, dark circles may appear under the eyes, and the eyelids are slightly puffed. The skin is dry and sometimes scaly, sleep is poor, nightmare is not infrequent, and restlessness is the rule.

TREATMENT

In many cases constipation in childhood might be prevented by the encouragement of regular habits. I wish to lay particular stress upon the mischief done to older children by lack of care in this matter. The child who goes to school is allowed to take his breakfast at an hour which leaves him barely time to snatch a hasty meal; much less to attend to the evacuation of the bowels. By insisting that he have his meal a half hour earlier, good digestion and daily evacuation may both be insured.

DIETETIC MEASURES

I wish to state that in my experience the dietetic measures, which may be of value and upon which many textbooks lay so much stress, are apt to be most unsatisfactory in many cases. The digestion at this age is easily upset, and the foods which exercise a laxative action upon the bowel are those which are most likely to disturb digestion.

In the case of the breastfed infant a change of food is never advisable unless the quality and quantity of the breast milk is insufficient. It is true that we may try to increase the protein or the carbohydrates in the mother's diet, but as a rule if any dietetic measures are to be tried it must be done by direct addition to the breast feeding. I see no objection to giving the infant once or twice a day some starchy food in the form of a well cooked cereal, such as farina or oatmeal.

A highly concentrated sugar mixture may answer the purpose, or a mixture of diluted milk with Benger's or Mellin's food, once or twice a day, with the breast feeding, or a bottle of acidulated milk. Water is also an essential, though many breast babies dislike it. In the artificially fed infant very often by a simple change in the diet it is possible to soften the stool and to produce free evacuation. In cases of fat constipation, reducing or removing all or nearly all the fat and increasing the carbohydrate may bring about a favorable result. Small doses of codliver oil are often helpful. Milk prepared with Mellin's food is often laxative. Of the starchy foods oatmeal is certainly the most laxative, and an oatmeal gruel or farina well cooked is often very efficacious.

In older infants a minimum amount of milk and eggs and a maximum of the coarser vegetables, such as spinach, beets, carrots, celery, lettuce and onions, will give results. I do not hesitate to give them to infants at a very early age. Apple baked or raw, figs, prunes and small pieces of bananas should be tried, and in some cases laxatives must be used. These I will discuss later.

In children past infancy dieting for constipation is one of the commonest causes of indigestion. The average mother has a profound conviction that it is bad to give drugs and will depend upon food which is said to be Nature's ideal, but with no result. Plenty of fruit, and more fruit, and various forms of bread are fed to children without benefit, only disturbing their digestion. I favor, therefore, the proper use of drugs in appropriate doses and at proper times.

Very often the doctor will prescribe a drug with directions "when required." This is a sure way to cause chronic constipation. Whatever drug is used, it should be given regularly, once, twice, or three times a day; in such doses as will keep the bowels open without purging. Its administration should be continued for weeks and months until the habit of regularity in the action of the bowel has become a fixed one. The time for omitting the drug is determined by attempting to drop one of the daily doses, or to reduce the dose after several weeks of treatment. If this is found not to alter the regularity of the bowel the other doses can gradually be diminished or omitted.

The choice of drugs will differ according to the age. The free administration of castor oil is harmful, increasing or even inducing constipation. The following drugs have served me well:

Hydrargri cum creta, one half grain three times a day; pulvis rhei comp., eleven grains three times a day; syrup of senna, thirty minims three times a day; liquid petrolatum, thirty minims three times a day; infusion of senna; powdered rhubarb; cascara with malt; and pituitrin.

Whichever of these various drugs is used, it is to be impressed upon the parents that regularity of the bowel must be procured and maintained, and the object of treatment is to establish a regular habit. It may require several weeks or months, but it usually can be successfully carried out.

A few words about the use of enemata and suppositories may be in order. They are less satisfactory for chronic constipation than treatment by mouth. The action of the bowel is made to depend on a mechanical stimulation, and when this has to be repeated for a long period the bowel will not respond to the less normal stimulant. Another objection is dilatation of the rectum and perhaps of the sigmoid. If an enema is to be used, and in some cases they are necessary, a small amount of fluid should be used, and olive oil is much to be preferred. Half an ounce of olive oil with three ounces of soapy water is sufficient.

Much can be said about mechanical means, such as massage and exercise. Biweekly treatments with the mercury quartz lamp for a few weeks will sometimes cure obstinate chronic constipation.

2009 Pine Street.

Renal, Ureteral, and Urethral Calculi

Report of a Case in a Child Eight Years of Age

S. WALLENSTEIN, M.D.

Baltimore, Md.

In reviewing the literature of this country one is struck with the lack of case reports on this subject. Dun (1), Charvin (2), Rafin (3), and others think that children seldom suffer from stone in the kidney. Dun cites Henry Morris who collected two hundred cases of operation for renal calculi between 1883 and 1893 and in only one case was the patient under ten years. Bokay (4), Civiale (5), and others think that lithiasis is common in children. Young (6) also disagrees with the clinicians who hold that renal calculi are rare in early life and believes that they are evidently at fault. Thompson (7), Canton Hospital, China, found during a period of nine years, 1911 to 1919, 585 cases of calculus of the urinary organs; thirty-eight per cent. of this series were in children under fifteen years of age. Thomas and Tanner (8) in this country collected 203 reports of infants and children with urinary lithiasis. Collins (9), who carefully studied the foreign literature and gave us the most valuable contribution on this subject, asserts that there is a paucity of case reports of renal stone in infants discovered and treated surgically during life.

The case I wish to report is one of renal, ureteral, and urethral calculi in a boy eight years of age. I was called to see the patient on February 7, 1925, at 1 a. m., in consultation with his family physician, who stated that the child had blood and pus in the urine which dribbled at times and that for the past twelve hours the child had suffered excruciating pain on attempting to void. He therefore felt that the child had a stone in the bladder. A cursory examination at the patient's home revealed that we were dealing with a deaf mute who was manifestly in extreme agony. After the hypodermic administration of morphine gr. 1/6 and atropine gr. 1/150 I proceeded with the examination and found that the bladder extended two fingers' breadth above the umbilicus, and a calculus was definitely palpable at the root of the penis. An attempt was made to pass a catheter which was arrested at this point. The child was then taken to the West Baltimore General Hospital, where an external urethrotomy was at once performed and a calculus 2 cm. by 1 cm. weighing 25 gm. was removed and about 1200 c.c. urine escaped. A retention catheter was then inserted and the wound closed with a few catgut sutures. On the fourth day the wound was practically healed and the catheter removed. An x ray plate was taken and showed a calculus in the bladder and a great number of large calculi in the left kidney.

A combined phthalein intramuscularly gave twenty-six per cent. for two hours and five minutes. A cystoscopic examination was done and to our surprise the calculus which was supposed to be in the bladder was found in the intramural portion of the right ureter. A number 6 catheter was introduced after considerable difficulty and a phthalein from the right kidney showed twenty-six per cent., proving that the left kidney was functionless. The blood chemistry was within normal limits and the Wassermann was negative. I then decided to watch the child for several weeks, during which time the x ray examinations were repeated several times and the results confirmed. On February 28, 1925, a suprapubic cystotomy was done and the calculus removed. The wound was closed, and a small drain inserted to the bladder and a retention catheter introduced. The suprapubic wound healed rapidly, but I again decided to wait and give the child an opportunity to build up a bit until March 27, 1925, when a nephrectomy was successfully performed. Graded operative interference was definitely indicated in this case and in no small measure was responsible for its successful completion. Rankin's (10) article on graded abdominal operations should be closely followed in genitourinary surgery as well.

The family history was unimportant; there was no history of stone in the family. His personal history is rather significant. The child, at birth, weighed ten pounds, was bottlefed after the third month. He had suffered from supposed intestinal

colic the greater part of the first year. He had none of the infectious diseases of childhood, but had convulsions and fits at four years of age for which he was admitted to a hospital. He stayed eight days at the hospital and his condition was diagnosed hydrocephalic imbecile. On examining

Fig. 1.

Fig. 2.

Fig. 1.—Kidney bisected showing large triangular calculus measuring 3.75 c.m. x 2.25 c.m. x 2.25 c.m., almost completely filling the pelvis.

Fig. 2.—Each half of the kidney again bisected showing a great number of calculi within the calyces. Chemical examination by C. E. White—amorphous phosphates covered by triple phosphates.

the chart one noticed that the child ran a septic temperature ranging from 99° to 101°, and that the uranalysis revealed a heavy albumin ring, alkaline reaction, a moderate amount of red blood cells and pus cells. Apparently no effort was made to account for these urinary findings. A parallel case is cited by Aleksinski (11); his patient had nervous fits at two years which were never diagnosed; however, his patient had no blood nor pus in the urine.

HISTORICAL NOTE

The development of renal surgery, particularly that of the stone kidney, is very interesting. From the days of Hippocrates, who records nephrolithiasis with great accuracy, the surgery of the stone kidney made very slow progress (12). The first operations ever ventured on the kidney were incisions for the drainage of pus, evidently for perinephritic abscess. Along about the eleventh century operations were performed on the bladder for the removal of urinary calculi. Even Guy de Chauliac (13), the most distinguished authority on surgery during the fourteenth and fifteenth centuries, held the view that renal calculi were formed from sand in the kidney, offers a number of medicines for dissolving them, and if unsuccessful, to remove the calculi only when they have descended into the bladder. For many centuries there was great opposition to the removal of stone from the kidney, because in doing this it was thought that the kidney would be destroyed, and that life was not possible without a kidney. This opinion was held for many centuries in spite of numerous successful animal experiments. In 1881 Czerney performed the first pyelotomy, which was soon followed by a nephrotomy by Dominic de Marchitti. Henry Morris performed several nephrotomies proving that calculi could be removed by incision through the renal parenchyma, and therefore proving that it was possible to save the kidney from the destructive influence of stone without sacrificing the organ. The first intentional nephrectomy is recorded by Simon of Heidelberg, but only after a number of nephrectomies were performed by mistake, mistaking the kidney for an ovarian tumor (14). For many years pyelotomy was the operation, by preference, it then yielded to nephrectomy for a great number of years, but now once more pyelotomy is the operation of choice. Recently, Goldstein and Carson (15) performed extensive experiments on dogs, bisecting the kidney from pole to pole and closed the wound by pressure without suture and proved by numerous pathological specimens that the method entailed no damage to the kidney.

ETIOLOGY

In just what way renal calculi originate is a problem; their constituents are always present in the urine, but the reason they crystallize out in some cases and do not in other cases is still to be solved (16). Possibly there is more than one single factor concerned in stone formation. Williams (17) enumerates the older theories. The theory of overplus salt content by virtue of increased elimination or high concentration of salt in the urine. The theory of organic nucleus may favor aggregation, but not precipitation. He further pretends to prove that lithiasis is secondary to fermentation, the ferments being elaborated by microorganisms and not by the body cells. Shade's (18) work on the origin of renal calculi furnishes an explanation based on scientific facts. Shade calls attention to the fact that if uric acid is deposited on fibrin no amount of water will dissolve it because fibrin belongs to a class of substances termed irreversible colloids. There are present in the normal urine colloids, mucin, and urochrome. These colloids are reversible, i. e., after having passed out of solution they may under changed conditions of reaction be again taken in solution. Irreversible colloids are present in the urine in pathological conditions only. Fibrin is the characteristic representative of the group of irreversible colloids. It appears in the urine as the result of hemorrhage or inflammation (19).

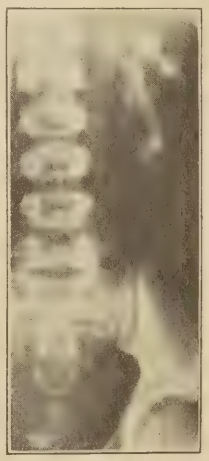

Fig. 3.—Plain x ray plate of the genitourinary tract, showing a number of calculi in the left kidney, and one calculus in the intramural portion of the right ureter.

It is well known that bacteria and toxins are constantly being absorbed into the circulation from the throat and bowel and excreted by the kidneys, without causing gross inflammatory changes, but it is not unlikely that lesser degrees of reaction may be induced with the liberation of fibrin which is the genesis of lithiasis. Cuturi's experiments support this view. Cuturi (20) determined from his animal experiments three very potent conclusions: 1. Bacillus coli reaching the healthy kidney by way of the blood stream causes no lesion. 2. Bacillus coli in the kidney complicated by calculus provokes

pyelonephritis and pyonephrosis. 3. Experimentally by separation or ligation of the rectum for twenty-four hours one obtains a pyelonephritis by the passage of Bacillus coli to the kidney by way of the blood, after ligation of the ureter. Bumpus and Meisser (21) of the Mayo Clinic have recently isolated an organism with marked selective affinity for the kidney. These live bacteria have been placed in devitalized teeth of animals and in several months renal calculi appeared.

Distribution.—Common in India, Egypt, China, Central Asia, and very prevalent in the eastern colonies of England. Although urinary calculi are moderately frequent in the United States, the disease does not appear to be endemic.

Race.—It is curious but nevertheless a fact that there has not been a single case in the negro at the Johns Hopkins Hospital; Howard Kelly in his broad experience has never seen renal calculi in this race. If infection plays any rôle, why is the colored race exempt?

Heredity.—Although in England there are a number of cases on record with definite hereditary and family history of stone, however, in this country it may be said to play an ill defined rôle.

Age and sex.—In this country it occurs in the early and midadult life. In Egypt, England, and China the disease is very common at all ages and in both sexes, males slightly more liable than females.

Food and drinking water.—These play an important part; hard water (calcium salts) must be avoided. That hard water is a factor in the production of stone may be noted from the fact that since the surface wells were closed and softer tap water was introduced there is a marked diminution of the disease in South Staffordshire (22).

Infection.—Collins (23) thinks it would be difficult to believe that infection plays any considerable part in the origin of stone during uterine life or in the very young infant. Martha Wollstein (24) thinks that faulty metabolism and infection in the mother may be the underlying causes of renal calculi.

Associated infectious diseases of children.—Joseph (25) maintains that thirty per cent. of his cases were associated with diseases of the respiratory tract, and twenty-five per cent. were associated with diseases of the alimentary tract; these facts are not to be lost sight of in our diagnosis of renal calculi.

Contributory factors.—Stasis of urine from obstruction may cause calculi. Frontz (26) says that congenital valves of the posterior urethra causing urinary retention in children may cause vesical and renal calculi. English (27) maintains that congenital narrowness of the urethra in children under two years of age is a factor in lithiasis. Hunner (28) believes that strictures of the ureter are often responsible for renal calculi.

PATHOLOGY

The pathology of stone in the kidney is the result of two factors: obstruction, or obstruction plus infection. We therefore have aseptic and infective lesions. Under aseptic lesions we have a chronic nephritis which depends upon the original cause of the lithiasis and is aggravated by the calculus. It is a diffuse nephritis possibly commencing in the epithelial lesions and accompanied by interstitial changes. At first the kidney may appear normal, or increased in size, later contracts and becomes granular, the capsule becomes adherent and small cysts may form. Later advanced interstitial nephritis with atrophy or hydronephrosis and then atrophy occurs. Perinephritis may also follow. Infection of the stone kidney may take place by the blood stream, or may be ascending. In the great majority of cases the infection is hematogenous. Pyelonephritis, pyonephrosis, and perinephritis may occur. Calculi have been found coexisting with malignant growth of the pelvis. Bugbee and Martha Wollstein (29) in a study of the pathology of the urinary tract in infants performed five thousand autopsies, and among other pathological conditions from birth to five years of age found calculi in 113 infants. The fact that many calculi were found in infants a few months old shows that calculi may be present from birth, and it is fair to assume that they are more common in infants than has generally been supposed, and that many an indefinite colic is due to lithiasis.

SYMPTOMATOLOGY

The symptomatology of nephrolithiasis in infants and in young children assumes many and varied forms. 1. The type with reflex nervous irritation, causing vomiting, and convulsions or nervous fits resembling chorea. 2. The type with toxic manifestations causing coma (uremic). Although many of the acute infectious diseases of childhood are ushered in with convulsions, it behooves us to bear in mind nephrolithiasis, for it is a common manifestation. 3. Those with contractions of the abdominal muscles having colic not unlike the intestinal colic of infancy. 4. Those with definite symptoms of renal colic of the adult type. In some cases there are few symptoms and of quite an indefinite nature, particularly in infants and younger children. We, therefore, must depend largely upon the history past and present, which history is our chief source of information. The younger the child, the less reliance can be placed on its subjective symptoms.

It is important to determine whether the child is prone to digestive disorders or disorders of the respiratory tract as these are often associated with renal calculus. Renal colic in the infant presents an entirely different picture from that of the adult. The acute pain caused by the calculus in its attempt to descend to the bladder is usually ushered in by vomiting and a series of convulsions, and in the older children nervous fits characterized by irregular and spasmodic muscular movements. This reflex irritation is due to the unusual susceptibility of the nervous system in infancy and childhood early. At times the convulsions may be due to the toxic influence of urea retention. In older children there may be localized tenderness and pain over the affected region, frequent urination, retention or suppression. Hematuria, unlike that of the adult, is rare. Pyuria, chills, and fever depend upon infection coexisting. While it is true that both convulsions and colic are largely of intestinal origin, it cannot be denied that in childhood both are frequently of renal origin.

DIAGNOSIS

The diagnosis of renal calculus in the infant is by no means easy. Calculi may be present without giving any signs, more often the signs are present but unrecognized and misinterpreted. However, a painstaking history and physical examination are very helpful. Too often chills, high and fluctuating temperature, and pyuria are dubbed pyelitis without any further study; likewise, colic is too often ascribed to the intestines. A complete uranalysis including a careful microscopic examination for blood, pus and infection is essential. X ray of the entire genitourinary tract will almost always reveal a calculus. Carl Beck (30) says that by means of x ray a definite diagnosis in suspected lithiasis can be made in each and every instance. A stereoscopic examination must be done when shadows are present in the ureter. Cystoscopic examinations should be done, this is successfully accomplished in infants a few days old. This procedure presents no more difficulties nor is associated with any more risk than that in the adult. Why not give the infant the benefits resulting from a thorough examination. Hinman (31) properly said that it is a greater error to miss making an early diagnosis through neglect of proper examination than to mistake the indication and unnecessarily subject the child to the examination.

TREATMENT

The treatment is essentially surgical. Renal calculi lead to greater destruction of the renal tissues than any other surgical lesion. In all cases delay means nephrectomy whereas a conservative procedure may have sufficed at an earlier stage. The views of continental urologists, Brongersma, Tardo, and others (32) are largely in accord with those of American urologists. Pyelotomy is the operation of choice where possible. Nephrotomy is often followed by infection, necrosis and late bleeding with partial destruction of the function of the kidney. There are unquestionably many cases where nephrolithotomy is indicated, such as of cortical stones firmly fixed in the minor calices. Brash and Judd (33) advise the combined pyelonephrolithotomy in cases in which the calculus is not readily accessible through the pelvis. In ureteral calculi manipulations with ureteral catheter, or indwelling catheters for a short period should be given a thorough trial. Where there is an extensive infection coexisting with the calculus, or where there are many calculi and the phenolsulphonephthalein is below ten per cent., nephrectomy is indicated.

SUMMARY

Report of a case of bilateral lithiasis, renal, ureteral, and urethral, in a male, eight years of age, necessitating the following operations: External urethrotomy, suprapubic cystotomy, and nephrectomy. Patient had an uneventful recovery.

1. The general practitioner as well as the pediatrist is not availing himself of the advantages and opportunities offered by the genitourinary surgeon in the diagnosis of lesions of the genitourinary tract in children.

2. There are entirely too many cases of calculus diagnosed as pyelitis and intestinal colic in children.

3. Pyuria alone is sufficient indication for cystoscopic study.

4. There is no more difficulty nor danger in doing a cystoscopic examination in a child than there is in an adult.

5. The morbidity as well as the mortality will be curtailed if the child is given the benefit of a complete urological examination.

6. Early diagnosis of lithiasis may be relieved by a conservative operation, whereas delay means sacrifice of the kidney.

7. Graded operations are often indicated in multiple and bilateral calculi.

Treatment of Tuberculous Joints in Children

PAUL C. COLONNA, M.D.
New York

The treatment of tuberculous joints in children has in general been most discouraging. The duration of the disease and its persistent crippling deformities have made the surgeon regard its arrest or cure with pessimism. The adult patient presents a different proposition and a simpler solution, but the majority of bone and joint tuberculosis is found among children. The disease usually appears in the bone while its chief manifestations are evidenced in the joint. In about five thousand cases of tuberculous disease treated at the Ruptured and Crippled Hospital, seven eighths of the patients were less than fourteen years of age and about seventy-five per cent. were in the first decade. The disease is rare before the age of two, most of the cases occurring between three and five.

In spite of a few who strongly advocate an early operation, most surgeons at present prefer to pursue a more conservative course. The conservative advocates consider the time element as a negligible quantity in the treatment of children. The remarkably successful results of Rollier in Switzerland and groups of surgeons in France, England, and America certainly bespeak in favor of the socalled outdoor treatment.

One of the earliest treatments must have been rest in bed. Meanwhile, in spite of careful nursing and good food, contractions developed and sinuses appeared, thereby convincing physicians that there must be a better method of treatment. Later, braces were introduced to prevent the patient from becoming hopelessly bedridden. Still the disease

progressed and as a further aid in the prevention of deformity, plaster of Paris came into use. The use of traction alone or in combination with these other agents also was a great step in the reduction of muscle spasm and pain. Some of the joints so treated became ankylosed, and out of these results grew the idea that a stiff or ankylosed joint in good position was the most that could be desired.

Absolute absence of the normal function of a joint is bony ankylosis while its mobility is a physiological function. Because a part is or has been diseased, should it mean a loss of *all* motion? Should it mean *absolute* fixation of the joint either attained by operation or induced by persistent and continued immobilization with plaster?

Based on this reasoning a number of fresh air homes for bone and joint tuberculosis in children have been started. The increasingly successful results of these outdoor hospitals seem to prove conclusively their value to the community. Jones and Lovett even state in their book that in the future a children's hospital in the town limits will be looked upon with forebodings. The best known of these outdoor hospitals is that one established about twenty years ago by Rollier in the mountains of Switzerland, over five thousand feet above sea level. Another equally interesting is the Seashore Clinic at Berck Plage, France. Whether seeing the deeply tanned, mahogany colored skin of Rollier's patients, or one of the six thousand patients being treated at the seashore in France, one is struck by the robust condition of the patient, the excellent tone of the muscles, and, what is most remarkable, the range of painless motion in the affected joint. One school stresses the benefit of the mountains in a high altitude. Another gets excellent results without mountains and at sea level.

The aim in all these cases is mobility. It is not obtained in all cases, but is secured in a larger proportion than one would think possible after seeing and believing that ankylosis in a good position is the most one can hope to give these patients. Splinting and traction are not neglected, and though plaster is used very little, yet in the acute stage strict insistence is made upon the absolute rest of the joint from movement. The proper application of sunlight is greatly stressed, which in brief is a gradual exposure until the whole body has been tanned, using the early morning sun in preference to any other time. With the cardinal factors of rest, open air, and good food there is general agreement. These have been called the modern methods of treatment, but in reality they are a combination of previously known methods more intelligently applied.

Rest should be enforced, uninterrupted and prolonged, as both Thomas and Hilton taught. Rest is desirable so long as the febrile stage continues, just as in pulmonary tuberculosis. Rest in bed must be continued with proper splinting and traction so long as the spastic condition about the joint remains. The small amount of pain complained of in the cases seen at Rollier's clinic was remarkable, but in no case seen was the part absolutely immobilized. Rest with traction is not immobilization but a restriction of motion. We do not immobilize any other part when diseased, though we may try to put it at rest. We limit its activity, but do not immobilize. The old idea that ankylosis follows rest, though it be interrupted, prolonged, and continued, was dispelled years ago by Thomas, who stated that "the treatment of articular inflammation by enforced rest never has been nor ever will be a factor in producing true ankylosis. Stiffness and limitation of motion may result, but this is far more serviceable than any ankylosed joint to a child.

The time comes in these cases when weight bearing is to be permitted, and this time is most difficult to determine. After all signs of activity have disappeared, both by a physical examination and by repeated radiograms taken at regular intervals, all traction and apparatus should be removed from the part and a careful examination, including the exact measurements of movement possible in the affected joint, should be made. Then after the patient has been allowed to remain free in bed for a week, a socalled secondary diagnosis of restoration should be made. These tests should be repeated several times in the month before weight bearing is allowed and their results must be the determining factor in the future course of the surgeon.

Fresh air treatment is not a recent discovery and has been used for conditions other than tuberculosis, but at present there is a great deal of argument and study about the reasons for the benefit received. At least two factors, that of wind and sunlight, play an important part in all out of door treatment. Whether the benefit derived from the wind is because it is a cooling agent to the sun's rays and a tonic to the general constitution, as Rollier believes, whether its principal action is due to its velocity acting on the organism as a masseur would exercise the muscles by rubbing and stimulating the local circulation, which Calvé believes, or whether it is due to some other factor, it is certain that it is a most valuable ally in the outdoor treatment.

The reason for the benefit derived from the sunlight is also little known. We know that the short wave lengths, of which the ultraviolet are the most important, are stopped in the outer layers of the skin and produce marked pigmentation. In large doses the ultraviolet rays possess marked germicidal power, while smaller doses stimulate epidermal cells and produce pigmentation. Unless the strong penetrating long rays of the sun are checked by the cool moving air, the skin and body become too hot and loss of tone results. This is especially evidenced by the patient becoming irritable or drowsy when the sun treatment is too enthusiastically given.

The one tissue that does not appear to have been given proper credit is the skin. It is the first line of defense against invading organisms, but in addition it seems to possess some special resistance to the bacillus tuberculosis. The recent work of Griffith showing that "the attenuation of Bacillus tuberculosis is apparently the rule in skin lesions," would indicate that normally the skin possesses more resistance to this particular germ than other parts of the body affected by tuberculosis. Rollier believes that in the skin we have a tremendously potent factor, not only in arresting the disease but possibly in possessing the ability to produce an immunity to bone tubercu-

losis. Whatever importance the pigmented skin may possess or acquire, certain it is that the many attempts to give an indoor pigmentation by the ultraviolet or other lamp have not resulted in the pigmented skin possessing qualities as beneficial to the body as skin exposed to sunlight and wind.

Good food is essential and should be given as in all febrile conditions. Little meat is necessary at all times and all fattening foods should be avoided, and instead plenty of fruits and vegetables with an abundance of water should be given.

CONCLUSIONS

1. Conservative measures should be used in the treatment of tuberculous joints in children.

2. The restoration of function, rather than ankylosis, should be the aim in the great majority of these cases.

3. Open air hospitals for the treatment of tuberculous joints in children should be more generally established—preferably in the mountains or at the seashore.

59 East Fifty-fourth Street.

Anemia Infantum Pseudoleucemia (Von Jaksch)

SAMUEL A. BLAUNER, M.D.
New York

Gretzel in 1867 was the first to mention this condition, but it was not until 1889 that a clear clinical description was reported by Von Jaksch, with the result that his name is now identified with this condition.

Von Jaksch anemia is an anemia peculiar to early infancy and is characterized principally by a slow and progressive pallor, a large hard spleen, at times a large liver, and frequently by an enlargement of the superficial lymph glands. The blood picture is not pathognomonic, showing the usual picture of a secondary anemia with blood destruction and blood regeneration. The regenerative feature in this condition, however, is characterized by the constant presence of normoblasts, although other regenerative elements are usually present. The white cell elements are increased, more so than is usual in secondary anemia, and at times reach such a high count that with the marked anemia and large hard spleen, it is difficult to separate this condition from a true splenomedullary leucemia. The white cell elements are as a rule about evenly divided between the polymorphonuclears and the lymphocytes, although not infrequently the lymphocytes predominate. Eosinophiles are reduced and in the severer forms myelocytes are found.

There are many authorities who refuse to look upon this condition as an entity, and consider it merely a form of secondary anemia. It is true there are no striking pathognomonic symptoms and, furthermore, the underlying agent is unknown. The fact, however, that the spleen is constantly enlarged and frequently associated with a history of rickets and gastroenteric disturbances would probably indicate a toxic agent as an etiological factor. The toxic agent may not be the same in all cases, but it may be that the formative blood organs and filters, such as the bone marrow and the spleen, react under certain conditions as yet unknown, in a constant way producing this symptom complex. It matters little whether this condition is a true entity and is caused by a specific agent, but from the clinical side this picture is sharp enough to say that a certain group of secondary anemia forms a distinct picture of itself.

Beside the blood picture of a varying secondary anemia, the pathology has nothing distinctive. The spleen is large and hard with a considerable growth of connective tissue causing a gradual disappearance of the Malpighian bodies. At times there may be also present a perisplenitis. The liver often is enlarged and hard and shows an increase in connective tissue formation, but the liver cells themselves are unchanged. The superficial lymph glands may be enlarged and show evidences of a simple hyperplasia. The bone marrow is usually very red, with evidences of an active regeneration of the blood elements.

Von Jaksch anemia is usually evidenced in early infancy between the third and sixth months with a slow but progressive pallor. The child does not necessarily have to be emaciated and its weight may be up to standard, but it is flabby and soft. This pallor is peculiar, is not ordinarily seen in other anemias, and is difficult to describe. The spleen enlarges and becomes hard and may fill up the abdomen, causing a distinct protuberance. The liver too may enlarge, but not in proportion to the spleen and frequently the superficial lymph glands are also enlarged. Gastroenteric disturbances are common and not infrequently gastrointestinal hemorrhages occur, more so in this condition than in any other type of splenomegaly. Petechia and hemorrhages from other parts of the body may occur.

These cases may progress unfavorably until death ensues from some intercurrent condition or they may reach a certain stage and then proceed to a cure. Prognosis here is more favorable than in any other form of the distinctive anemia. This anemia must usually be differentiated from Banti's splenomegaly and Gaucher's disease. The history, time of occurrence, blood picture, and hereditary factors will all aid in the differentiation.

Case.—The patient, M. S., male, was seven months old at the time of the first observation, with a family history absolutely negative relevant to this condition. The child was a full term baby, normal delivery, and breast fed from the very beginning, with some table diet added to his régime latterly. One striking feature noticed by the mother was a progressive pallor coming on for the past four months,

so marked that it was noted by friends and relatives. During the same period the child was subject to gastrointestinal attacks and at times had a cough with slight elevation of temperature. There was no history of any previous infection or contagious disease. Ten days before admission the child had shown continuous tarry stools and vomited rather frequently after meals.

On admission the child was acutely ill, very anemic, with pale conjunctivæ and lips and a slightly jaundiced skin. The spleen was hard and one inch from umbilicus and the liver's free edge almost down to the umbilicus. Other examinations of body were negative.

The blood examination at the time of admission was: Hemoglobin, 16 per cent.; red blood cells, 1,200,000; white blood cells, 52,000; lymphocytes, 54 per cent.; polymorphonuclears, 34 per cent.; and transitionals, 12 per cent. A transfusion which was immediately ordered and given within three hours, increased the hemoglobin to 40 per cent. Three days later blood examination showed hemoglobin, 45 per cent.; red blood cells, 1,950,000; white blood cells, 6,200; polymorphonuclears, 43 per cent.; lymphocytes, 57 per cent. Several blood examinations at intervals of two days showed a steady improvement in the blood and after the last examination made two weeks after admission the hemoglobin was 62 per cent; red blood cells, 3,760,000; white blood cells, 14,000; polymorphonuclears, 36 per cent.; lymphocytes, 64 per cent. Bleeding time after transfusion was five and a half minutes and coagulation time one and a half minutes.

The interesting feature of this case was the rapid and almost spontaneous cure following transfusion. Immediately thereafter the child's general appearance was much improved, and although before transfusion it had passed tarry stools, these appeared practically normal the following day. Beside the general improvement in the child's appearance, it was interesting to follow the retrogression of the spleen and liver, so that two weeks following its admission to the hospital, except for a slight reduction of the red blood cells, the child was both physically and clinically well.

The Present Status of the Control of Scarlet Fever*

RALPH OAKLEY CLOCK, M.D., F.A.C.P.
Pearl River, N. Y.

During the past year there have been greater definite advances in our knowledge of the etiology and treatment of scarlet fever than in any of the other communicable diseases. Some of these advances are now sufficiently stabilized to permit of their being interpreted as important factors in the control of this disease. I propose to discuss briefly this subject under four divisions; first, etiology; second, skin tests; third, immunization with toxin; and fourth, serum treatment.

ETIOLOGY

For many years the hemolytic streptococcus was suspected and studied as the causative factor, because of its persistent presence in the throats of scarlet fever patients, and in blood cultures, and in the secondary complications such as otitis media, adenitis, nephritis, pneumonia and septicemia. This disease is all the more remarkable in that the organism penetrates the blood, so that there is a true septicemia, and yet the patient often recovers. In other diseases, if the organism enters the blood stream it means a fatal outcome.

One important point that has been brought out in the more recent investigations is that the disease is not transmitted through the skin, for the scales during the desquamation stage do not carry the infection, as was long supposed. The disease is transmitted only through air borne droplets of saliva or nasal discharges, or by contact with articles soiled with saliva, nasal secretions, or the discharge from some secondary complication, such as otitis media; or through contaminated milk.

A few years ago Dochez and his coworkers developed a method for the differentiation of the biological types of streptococcus hemolyticus. This led to further studies of the type that had been found to be associated with scarlet fever. Dochez finally demonstrated that the type of hemolytic streptococcus found in the throats of scarlet fever patients was a specific type which could be differentiated from types causing other forms of angina and general septic conditions. The work of Dick and Dick showed that the scarlet fever streptococcus may be distinguished by growing it in broth and determining whether or not it produces a soluble toxic substance in the filtrate which will give a skin test neutralizable with convalescent serum.

Many attempts were made to produce scarlet fever in animals, including dogs, monkeys, rabbits, rats, mice, hogs and guineapigs. By improved technic, Dochez was able to produce the disease in hogs and guineapigs, more especially in guineapigs. But animals proved unsatisfactory for producing conditions that could be definitely identified as scarlet fever, and so Dick and Dick used human volunteers for purposes of producing experimental scarlet fever.

SKIN TESTS

In the course of their investigations the Dicks attempted to produce skin reactions with the same culture of the hemolytic streptococcus that had caused the disease. They injected intradermally small quantities of the toxin prepared by growing the scarlet fever streptococcus in broth, and finally they perfected a skin test similar to the Schick test. This skin test, which is now known as the Dick test, is made by injecting intradermally in the forearm

*Read before the Ramapo Clinical Club at Suffern, N. Y., March 26, 1925.

0.1 c.c. of scarlet fever toxin in correct dilution and using a similar amount of heated toxin in the same dilution for a control. A positive reaction occurs in twenty-four hours and is indicated by a red, inflammatory area about two centimetres in diameter. Unlike the Schick test, however, the reaction from the Dick test fades rapidly after twenty-four hours; so the test must be read twenty-four hours after it is made and not four days afterwards, as in the case of the Schick test.

The Dick test seems to be reliable for detecting those persons who are susceptible to scarlet fever, but it is complicated by the fact that one negative reaction does not always seem to indicate immunity. In our studies we have reapplied the Dick test at intervals of a few days on the same persons, using the same toxin; and we have observed definite positive reactions in persons who occasionally showed a negative reaction. Moreover, such negative reactions were both preceded and followed by positive reactions within a few days. Furthermore, among a series of 286 negative reactors, in eight persons scarlet fever developed subsequently. Therefore, it would seem advisable for all persons showing a negative Dick reaction to be retested and for at least two negative tests to be obtained before considering the person immune to scarlet fever.

The phenomenon of negative reactors among susceptible persons is to be explained by assuming that the scarlet fever toxin has weak binding power with the tissue cells, in which capacity this toxin differs from diphtheria toxin; for, as you all know, a negative Schick reaction means that the person is positively immune to diphtheria. We may, therefore, assume that some intradermal injections of scarlet fever toxin are made in areas of the skin where, for some reason, the toxin is absorbed too quickly to permit of its characteristic irritating effect on the skin cells being produced.

IMMUNIZATION WITH TOXIN

Another factor that still remains to be satisfactorily disposed of is the matter of immunization with the scarlet fever toxin. When the toxin is used for immunization, the dose employed is equal to a certain multiple of the amount of toxin used for the Dick or skin test. Hence, the dose is expressed as consisting of a certain number of skin test doses of toxin. At first comparatively small doses were used, namely, 125, 250 and 500 skin test doses, given subcutaneously at intervals of one week similar to diphtheria toxin antitoxin. Out of 1,500 children so immunized, when the Dick test was reapplied two or three months later, about fifty per cent. of them still showed positive Dick reactions, indicating that no immunity had developed. In another series of 900 cases in which the dose used was 125, 500 and 1,000 skin test doses, at the end of three weeks retesting by the Dick method showed eighty per cent. negative reactors or eighty per cent. immunity. Again, in a series of 3,000 cases, the immunizing doses consisted of 1,000, 2,000 and 4,500 skin test doses; and, after six weeks, fifty per cent. were still susceptible, as shown by retests. On the other hand, out of ninety-seven positive reactors who were subsequently given the immunizing treatment with toxin, in sixteen scarlet fever developed before the immunizing treatment was completed; in nine after the first immunizing dose; in four after the second dose; and in three after the third dose. The doses used in this series were 125, 250 and 500 skin test doses.

In some cases, initial doses of 1,000 skin test doses have caused reactions simulating true scarlet fever: rash, fever, nausea and vomiting and typical strawberry tongue. Similar symptoms have resulted from even smaller doses. Zingher in New York is now giving four doses for immunization; beginning with 250 skin test doses, followed by 1,000, 2,000 and 3,000 skin test doses. He believes that the small initial dose confers sufficient immunity to protect against constitutional reactions when the larger doses are subsequently given. Nesbit in his work in the public schools of Gary, Indiana, used 4,000 skin test doses for the final dose.

Hence it would seem that the best dose for immunization had not as yet been definitely established. This is one of the problems that we are now trying to solve. Moreover, we do not yet know how long the immunity will last from the toxin injections; but there is reason to believe that the immunizing treatment has already produced results well worth while, although improvements doubtless will be made. Unquestionably, immunization with scarlet fever toxin is useful in controlling epidemics of the disease in institutions; for the immunity produced is usually of sufficient degree to check the outbreak in two or three weeks. Moreover, the immunity seems to be of sufficient duration to make it of clinical value in institutions and communities where scarlet fever is prevalent.

SERUM TREATMENT

In 1918 Schultz and Charlton observed that when one c.c. of serum from a normal human being or from a person convalescent from scarlet fever was injected intradermally into a patient with acute scarlet fever, a local area of blanching occurred and persisted. Mair, and more recently Dochez, called attention to the fact that in scarlet fever the general symptoms and rash depend upon the presence of a toxin in the blood stream and recovery occurs simultaneously with the formation of an antitoxin. Hence, if convalescent serum is injected into the skin of a patient in the acute stage of scarlet fever, the skin will be blanched due to the antitoxin in convalescent serum neutralizing the toxin in the tissues at the point of the injection.

Dochez states that sixty per cent. of all adults are immune to scarlet fever, for their serum will blanch the scarlet fever rash and must, therefore, contain antitoxin. Immune horse serum will blanch the scarlet fever rash in one hundred per cent. of scarlet fever cases that have lasted sixty hours. After the disease has persisted for eighty hours, the immune horse serum will cause blanching in only twenty per cent. of cases.

The new scarlet fever streptococcus antitoxin, which has just been licensed by the United States Government, bids fair to make the year 1925 memorable in the history of medicine. This new antitoxic serum will rob scarlet fever of its terrors, for the clinical results of its therapeutic use are nothing short of miraculous.

Credit rightfully belongs to Dochez for having first produced an antitoxic horse serum against the scarlet fever streptococcus, and for having tested its capacity to neutralize the rash locally in the skin in human cases of scarlet fever. Credit must also be given to Dochez for having demonstrated, with the cooperation of Blake, the clinical value of the serum in the curative treatment of scarlet fever.

Scarlet fever streptococcus antitoxin has three uses: first and foremost, is its therapeutic use in the treatment of the disease; second, it may be used under certain conditions as a prophylactic measure; and third, its diagnostic use by the blanching test.

The benefit resulting from the injection of scarlet fever streptococcus antitoxin is so marked that the physician is justified in using the antitoxin in all but the very mildest types of scarlet fever. The beneficial results consist not only in the prompt relief of toxic symptoms, but also in the lessening of the number of secondary complications. It is highly important to use the antitoxic serum early; for its effect in preventing secondary complications is most marked if used before the third day of the disease.

Blake has shown that the antitoxin must be used within the first seven days of the disease if beneficial results are to be expected; because normal antitoxin may be demonstrated to have replaced the toxin in the patient's blood from the ninth to the twelfth day of the disease. Hence, if the antitoxin is administered after the seventh day its beneficial action is doubtful, because the patient is then deriving benefit from his own normal antitoxin.

For all except toxic cases, the antitoxin may be given intramuscularly in the gluteal region; but in toxic cases it should be administered intravenously. The dose used by Blake has been from thirty to eighty c.c. in children and from forty to one hundred and fifty c.c. in adults.

Obviously the dose of this antitoxin depends upon the severity of the disease. In the clinical trials thus far recorded of the scarlet fever streptococcus antitoxin, the dose in early cases of both moderate and severe scarlet fever has been a single *intramuscular* injection of fifty c.c. of antitoxin having a potency such that each cubic centimetre will neutralize 5,000 skin test doses of toxin. This has been followed by prompt and complete relief within twelve to twenty-four hours. In severely toxic cases, higher doses (up to 150 or 200 c.c.) should be used if the antitoxin is given intramuscularly; but fifty c.c. is sufficient if given *intravenously*. If the antitoxin has a higher potency than capacity to neutralize 5,000 skin test doses of toxin to the cubic centimetre, a corresponding reduction in the volume of the dose may be made. For small children (under fifty pounds), one half of this dose is probably adequate. At present a unit of antitoxin has not been established, but probably the amount that will neutralize 1,000 skin test doses of toxin will be adopted as the unit in the near future. Then the dose can be expressed in units rather than in cubic centimetres.

The effects of the antitoxin are very striking. The rash begins to fade in six hours and the temperature drops; in twelve hours the temperature may reach normal. There is a drop in the leucocyte count and in the pulse rate, and rapid subsidence of the angina. Toxic symptoms improve in twelve to fourteen hours after intramuscular injections of the antitoxin and within three to four hours following an intravenous injection. Children often sit up and play the next morning. In adults, also, the return of well being is apparent within twenty-four hours.

Blake recently reported a series of ninety-three cases in which the antitoxic serum treatment was used. In these, ninety-two patients were cured and one died. In the fatal case the patient was treated with antitoxin late in the disease. In only ten did secondary complications develop. Hence, there seems to be indirect benefit on septic complications.

In some patients serum sickness follows the use of the scarlet fever streptococcus antitoxin just as it did in some patients when antidiphtheritic serum was used in the treatment of diphtheria before refined and concentrated antitoxin was available. Such symptoms, however, are usually of short duration and require only local treatment with some bland evaporating lotion.

The prevention of scarlet fever after exposure is somewhat complicated. In case of definite exposure the Dick test is made as soon as possible and, at the same time, a culture from the throat is made on blood agar plates. If the Dick test is negative, nothing further is done; for the person is considered to be immune. On the other hand, if the Dick test is positive, the next procedure depends upon the throat culture. If the plates show no hemolytic streptococci, active immunization with scarlet fever toxin is carried out. In case the throat culture shows the presence of hemolytic streptococci, a prophylactic dose of ten c.c. of the scarlet fever streptococcus antitoxin is given subcutaneously, preferably in the interscapular region. In small children (under fifty pounds), a prophylactic dose of five c.c. is probably sufficient.

DIAGNOSIS

The blanching test, or Schultz-Charlton phenomenon, has been made use of to differentiate the rash of scarlet fever from the eruptive characteristics of other infectious diseases, such as confluent measles, typhoid fever, influenza, and the drug rashes. This test is carried out by injecting intradermally 0.1 to 0.2 c.c. of antitoxin at a point where the eruption is most intense. After six to twelve hours, the rash—if it is due to scarlet fever—is definitely and completely blotted out in a zone of varying size surrounding the point of injection. The area is usually oval in shape with clearly defined edges, and within this zone the raised points of the eruption disappear and the skin becomes smooth. The blanched area persists throughout the disease and is protected from desquamation. In other words, there is actually a local cure in the blanched area, due to neutralization of the toxin in the tissues by the antitoxin which is injected. The most favorable time for obtaining the blanching phenomenon is during the second day of the eruption.

Scarlet fever streptococcus antitoxin unquestionably marks the greatest advance in preventive medicine during the last decade. Clinical trials indicate that this new product is destined to prove as important and valuable a factor in the control of scarlet fever as is diphtheria antitoxin in diphtheria.

Historical Medicine

Cicero in Search of a Garden

A Study in the Dubieties of a Great Roman

CHARLES L. DANA, M.D.,
New York

> And all without were walkes and alleyes dight
> With divers trees enranged in even ranks;
> And here and there were pleasant arbors pight,
> And shadie seates, and sundry flowering bankes,
> To sit and rest the walkers' weary shankes.

In the spring of the year B. C. 45 and A. U. C. 709, Marcus Tullius Cicero was in the lowest possible state of mind. His party, the senatorial party who called themselves the optimates, had been defeated. Its leader, Pompey the Great, had lost the battle of Pharsalia and been slain. Julius Cæsar was triumphant, and completely master of the political situation. Although Cicero had sided with Pompey, he had been treated well by Cæsar despite this, and had been allowed to return to his home in Italy. Here and then his troubles began to accumulate.

One of the first things he did on reaching Italy was to divorce his wife, Terentia, apparently because she had not managed his affairs satisfactorily during his absence in Greece. Then at the age of sixty, he married his ward, a young woman named Publilia. He soon put her away because, it is supposed, she was not sympathetic over the death of Tullia, his daughter. After their separation she asked to visit Cicero. "See what a nuisance," Cicero writes.

His son Quintus was not very satisfactory; and his son-in-law, Dolabella, was a dissipated youth, and a follower of Cæsar. His domestic affections were entirely centred upon Tullia, his only daughter. Tullia was about thirty years old, and had no children. She is often mentioned in Cicero's letters, and always with some term of affection—he often called her Tulliola, his little Tullia. She had been so badly treated by her husband, Dolabella, that she got a divorce; then a few months later died in childbirth.

This was in February, B. C. 45. Cicero was inconsolable. He retired to his villa at Astura, secluded himself from visitors and friends, and poured out his grief in letters to his friend Atticus. He writes him that he sleeps badly; that he goes into the woods in the morning and stays there all day. The cheerfulness with which he used to temper the sadness of the times he had lost forever. Nevertheless, he denies that he is "broken down." He evidently has no serious depression, like melancholia, for he occupies himself with writing important works during this period. He composes his *Consolatio,* also his *De Finibus,* and the *Academica.* He began also his *Tusculan Disputations,* his *De Senectute,* and *De Natura Deorum.* These things distracted his mind, he says, but did not relieve him.

Tullia died in February. In March, Cicero, while still in his seclusion, conceived the idea of erecting a shrine to her memory. This shrine (*Fanum*) was to be more than a monument or memorial; it was to be something sacred, and in the nature of a deification to his lost daughter. "I shall use all the opportunities of this enlightened age," he says, writing March 11, B. C. 45 (his *temporibus tam eruditis*), "to consecrate her memory by every kind of memorial borrowed from the genius of all the masters, Greek and Latin."

He now writes almost daily to Atticus about the scheme to which he says he had in a way consecrated himself. Atticus seems to give him his approval and cooperation. At first Cicero thinks that his island at Arpinum would answer, but later finds it too remote. The shrine must be in an accessible and public place. None of his own several villas would do, for they might change hands; and the shrine must be in a place which would be permanent and consecrated ground, forming a memorial for all time, and immortalizing the person of his Tullia. So he must find and buy a garden suitable for this purpose. Atticus begins to suggest different places, and send agents to see about their purchase; meantime, Cicero has conferred with artists and has approved of a design for columns by Clautius.

So the quest for a proper garden goes on. Cicero's temperament is marvelously shown. The place must not be too far from Rome, he says, and not too small; or on the other hand, too large and expensive.

Cicero begins to figure up how much money he can raise for his purpose. He thinks that Atticus can get six hundred thousand sesterces (twenty-five thousand dollars) out of Hermogenes; and Cicero himself has an equal sum with him. The rest of the money he must borrow, unless his debtor, Faberius, can be made to pay up. Thus the garden was to cost over fifty thousand dollars, and Cicero evidently meant to build an expensive memorial.

Throughout the spring of B. C. 45, March, April, May, and well into July, Cicero keeps writing, urging, begging Atticus to do something. But the trouble is always in getting the right kind of a garden. At first the task seemed easy. The gardens of Drusus were available and satisfactory. Then it turned out that Drusus was a hard man to deal with and his price was high. Cotta had a little place at Ostia, which seemed as if it might do, but finally it was considered too remote and small. He now decides also that he wants a "suburban garden," one which will be frequented by people who will presumably admire his shrine and be informed of the merits of his daughter. He finds that for his purpose the gardens of Silius were preferable to those of Drusus; however, Silius refuses to sell.

During the course of his search he came to the conclusion that the garden and shrine might be a suitable place for his own declining years. With this idea in mind he investigates the lands of Damasippus and the villa of Coponius, which latter he says has a fine wood; but he does not care for woods in connection with a shrine, because few people visit a wood.

In May, he remembers that the law did not allow a person to spend more than a certain sum on architectural and sculptural ornamentation. An equivalent of this excess had to be turned over to the state. This gives further dubiety as to his garden. He finds, however, that he likes very much the gardens of Clodia, a rich lady, who was out of the city and whom he fears may not be willing to sell. Lamia had a nice place, but also would not sell at the offered price. In fact, Cicero seemed to pick out places that either cost more than he thought he should pay or were not for sale, or did not suit.

In May, his mind turned towards his own villa at Tusculum as a last resort. He dreaded selecting this place, however, because his daughter died there, and he thought it would "open his wound" to live at such a spot.

By the middle of May, he rather centres his mind on the gardens of Scapula. These were for sale, but they were to be put up at auction, and Cicero arranged to attend this auction and buy, he says, "if it is safe to do so." His preferences, he writes to Atticus on May 11th, are first the garden of Scapula, then those of Clodia, Drusus, Cusinius and Trebonius. He writes to Atticus nearly every day about the various gardens, and about raising money to pay for them. Even up to the last of June he says, "By all means let me have a suburban garden."

The auction of Scapula's garden is fixed for a period early in July, and he writes on July 5th about attending it. The auction was postponed, however, and apparently Cicero did not eventually attend. There is but one further notice of buying a garden in his letters. In fact, there were no letters to Atticus between early August and December, perhaps because they were together in Rome.

During these later months of June and July, Cicero was busy writing and publishing some of his most important works. Cæsar was planning to come to Rome in August, and there was much discussion as to Cicero's attitude toward the Dictator, and as to his again participating in politics. Between his book publishing and his politics, the matter of the garden rather fades away. The last mention of it is in July, when he still speaks of getting a suburban garden.

Atticus probably had disapproved of the plan from the start, but did not wish to hurt Cicero's feelings by opposing a project so dear to his heart. However, he easily managed to find objection satisfactory to Cicero's dubiety as to every special place; and he made Cicero perhaps finally realize that a garden was too expensive and that there was a certain impropriety in trying to pay divine honors to a young lady who was only an amiable, affectionate and devoted daughter.

Although no garden is announced as bought, it is not impossible that Cicero did erect somewhere a shrine; for, in June B. C. 44, a year later, he writes that his business man, Eros, had set aside receipts from certain paying concerns, to be used for the shrine. *"Ad illud fanum depositum."* Let. XV-15.

Cicero's search for a garden is certainly the story of the workings of a dubious mind.

A phase of this was shown later, after Cæsar was killed, and Cicero was brought into relations with Antony and Octavianus. Cicero was consistently loyal to his belief in the sacredness of the Roman Constitution and of the Republic; and he also consistently attacked Mark Antony. But he could not settle his mind as to the opposing factors in Italy. He wasn't sure of Octavianus. He could not decide whether to leave the country and save his life or stay in Rome, work for the Republic and secure the cooperation of Octavius. He started once for Greece, and even had boarded a vessel, then turned back and went to Rome. He stayed and worked there too long, and the result of this particular dubiety was that the powers at Rome despatched a body of soldiers, caught Cicero as he finally was trying to leave the country and cut off his head and his hands, these being brought to Rome and presented to Antony.

Now while Cicero had in a striking degree the traits of a psychasthenic (dubiety and precisions), he was Rome's greatest constitutional lawyer, and its most eager pursuer of philosophy. He wrote verses in early life and was a very good poet and he first and alone made Latin a literary language. For his public work he was acclaimed father and savior of his country.

He was one of the very few really great men of that day who, while not exactly and entirely sincere, was genuinely and fundamentally honest and truly patriotic. He achieved all the honors of Rome's political life, having been questor, edile, prætor, consul, senator and governor of a province.

He was, beside all this, a man of great personal charm—witty, conversational, fond of his family, his friends and of city and social life. He entered into all the agreeable activities of both the socalled highbrow and lowbrow type. Always concerned for the health of others, he almost never refers to his own personal condition, and, while egocentric, he had no hypochondria.

He was tall, thin and active, but dyspeptic and lived on a diet.

Cicera was a great lawyer and debater, but he was never a good administrator and he seemed to lack personal initiative as he grew older.

Although he has been the subject of severe criticism by certain monarchical German writers (Drumann, Niebuhr), the majority of sound historians find few Romans who achieved or deserved more eminence than Tullius Cicero. They might well do this, for the Romans were rather stupid, dull, or uninteresting personalities.

Cicero was the cleverest personality of his age and he created a kind of oasis in a socially arid land. The Roman writers themselves, e. g., Catullus, Juvenal, Tacitus, all paid tribute to his memory. *"Salve, primus omnium parens patriæ appellate,"* said Pliny in his *Natural History.*

53 West Fifty-third Street.

Contributors to the Science of Medicine

Thomas Henry Huxley

Huxley was one of that band of mid-Victorian giants of science which included Darwin, Spencer and Tyndall. Huxley, like Darwin, spent some years on board ship studying natural history. He was one of the clearest thinkers and most lucid writers that ever lived, and while he did little original work, he did yeoman service in popularizing science and especially in explaining to the public the theories of Darwin. Lord Riddell contributes to *John O'London's Weekly,* May 2, 1925, an interesting sketch of the life of Huxley and pays him the compliment of saying that whatever power of accurate thinking or of writing he, Lord Riddell, possesses he owes largely to Huxley. He goes on to say that in some respects Huxley resembled Voltaire. He was the most prominent member of a brilliant group of educationalists who popularized science and taught people how to think and how to judge things free from dogma or bias. For thirty years dating from 1865, (Huxley was born in 1825) he was one of the star turns on the polemical stage, sharing the honors and holding his own with Gladstone, Disraeli, Bright, Spurgeon, and it may be added with Samuel Wilberforce and other celebrated performers of that time. No man was more admired or more abused. He was a sort of scientific prophet, preaching the advantage of unbiased inquiry and clear thinking.

Today, his type has disappeared. There is no one who can deliver the precise kind of goods that he provided. Perhaps this is because they are not wanted. The fashion has changed. The twentieth century does not enthuse about abstract ideas, religious discussions or scientific theories.

In 1860, however, there were ample opportunities for discussion and controversy. The evolution theory was setting all thinking persons and those with traditional religious views by the ears. The Darwinian theory upset the tenets of the Old Testament as to the creation of man and controversy waxed warm on the subject. It resolved into a fight between science and the churches and Huxley was the champion of science, and a doughty champion he showed himself. Huxley coined the word "agnostic" to label his attitude to what he considered unproven statements. He was not a doubter in the sense that he was not open to conviction, but he required extremely strong, in fact unassailably strong, evidence before he was convinced. Truth with him stood paramount and it is possible that he placed too much faith on what are termed facts. But he was an earnest inquirer and investigator and weighed evidence with the utmost impartiality of which a human being is capable. In a way he was selftaught, which is remarkable when it is considered how vast a store of knowledge he accumulated, although after all it is a better method of stocking one's brains than the methods followed in schools. At the age of twelve he is depicted as sitting up in bed at dawn reading Hutton's *Geology.* At the age of thirteen his inquisitiveness, or it may be more correctly termed his thirst for knowledge, was the cause of a serious misadventure. At a postmortem he attended he contracted blood poisoning which left a permanent mark on his health. When of the age of fifteen years and a half, he was apprenticed to a doctor, which was the vogue at that period. At seventeen he entered Charing Cross Hospital, having won an entrance scholarship and had a distinguished career as a student. He was only twenty when he published his first scientific paper. In the same year he joined the Naval Medical Service and was gazetted surgeon to H.M.S. *Rattlesnake,* which was told off to survey the Great Barrier Reef and New Guinea. On this expedition he did splendid work as a naturalist. He was made Fellow of the Royal Society at the age of twenty-five and four years later resigned from the navy and was appointed lecturer on natural history at the School of Mines, a position he held for thirty-one years.

His subsequent career was one of unchecked success, save that he made little money and suffered from ill health. He was given, as Lord Riddell says, practically every honor open to a scientific man. Huxley was a great zoologist, and his contributions to science related chiefly to zoology and to paleontology. He was one of the first to attack the system of classification formulated by Cavier, who divided the animal kingdom into four branches supposed to have been designed by the Almighty before the Creation. Huxley objected on the ground that this classification was based on mere theory, and that the only true method of classifying animals, insects and fishes was to examine and compare them. Huxley was a man of very great scientific attainments of which possibly he did not make full use; that is, that he rather took upon himself the rôle of explaining the scientific discoveries and theories of others than doing original work himself. He loved science for its own sake and when he had convinced himself that a discovery or theory, such, for instance, as that of Darwin's theory of evolution, was correct or based on sound premises, no trouble was too great to him to render comprehensible to the public the reasons for this belief. He was indeed Darwin's Boswell, not in the intimate sense that Boswell made known the life of Johnson, but in the sense that he made known to the man in the street the progress of science as indicated by Darwin's views and he did this in plain and clear language.

Thus the general public took his scientific attainments on trust and he was known to them as a popular writer, speaker and controversialist. If it had not been for Huxley, Darwin's views might have fallen flat except among the inner circle of scientific men. However, he wrote some excellent

small books on scientific subjects, and those on physiology and physiography had a wide sale. Perhaps his book on "Hume" in the *English Men of Letters* series was the best of his popular books. He had the gift of clear expression developed to the highest degree and used the most apt metaphors to illustrate and drive home his points. He hated loose thinking and loose expressions and distrusted politicians and political churchmen who to gain a temporary advantage over an opponent in argument were not averse from employing such means.

Huxley's views, or rather his manner of propounding them, would not have appealed to the people of these times. We are today tolerant to an extent which would have been anathema to the mid-Victorian philosophers who thought it their duty to lay down the law in a dogmatic way. The tolerance of the present day goes to such lengths that it is almost impossible for us to understand, the bitter feelings aroused by Darwin's pronouncements as to the origin of species and the descent of man, which antagonized to the point of overturning the long held beliefs founded on the Book of Genesis. Darwin and Huxley were stigmatized as atheists and sinners of the deepest dye and families were divided and friends separated in accordance with the views they severally took on the subject. Nowadays, churchmen in high office admit that there is something in the evolutionary theory and endeavor to fit it in with the teachings of the Bible.

It is to the lasting honor of Huxley that he was so great a lover of truth and held so strongly to his convictions that he never hedged or deviated by a hair's breadth from his beliefs and expressed himself in strong vigorous language, no matter whose susceptibilities he hurt. He died at the age of seventy, having been one if not the greatest factor in laying the foundations for the spirit of careful unbiased investigation, the keynote of modern science.

Lord Riddell in his sketch of Huxley makes somewhat of a digression from the main theme by drawing attention to the fact that Huxley lived in a dyspeptic age. Most of the well known philosophers of the mid-Victorian era suffered grievously from dyspepsia. Darwin, Spencer and Huxley were chronic victims of gastrointestinal disorders. However, in spite of this happening most of them reached the ordinary span of life allotted to mortals and some exceeded it considerably. Although Huxley was renowned throughout the world for his outstanding knowledge of science he made little money and was generally in pecuniary straits. As proof of the love and esteem in which he was held by his friends, in 1873 when his health was very bad Darwin sent him £2,100 contributed by eighteen of his friends. Huxley's name will endure as the great protagonist of the evolutionary theory; as an honest truthseeking philosopher, and as the man who did more than anyone to place science on a firm foundation, that of careful and impartial investigation, to take nothing for granted.

The Origin of Syphilis

CHARLES GREENE CUMSTON, M.D.

Geneva, Switzerland

Since the death of Iwan Bloch, the protagonist of the American origin of syphilis following the teachings of Professor Rollet, of Lyons, and his collaborators, Professor Sudhoff has attempted to accumulate proofs and arguments in favor of the precolumbian presence of the disease in Europe. Now Professor Gumpert comes to the front and taking up separately in succession the twenty-two propositions put forward by Sudhoff to assert his point of view, he shows beyond question that every one of them can be contradicted and this he proceeds to do. We have always regarded the precolumbian doctrine of Sudhoff as the weakest production of this learned historian of medicine.

Within the last few months Professor Barduzzi, of Sienna, has emitted the opinion that syphilis in Italy dates only from the epidemic of 1493. He maintains that the Spanish contracted the disease in America and brought it back with them to Europe. As proof of his assertions, Barduzzi puts forward the following documents: 1. Oviedo affirms that in 1493 he saw at Barcelona the companions of Columbus who had followed him on his three voyages to America and that he was able to verify the American origin of the new affection, which was horrible, contagious and lethal. With the exception of the Spanish this disease up to that time had not attacked any European. The soldiers composing the army of Gonzalve of Cordova transported the disease to Naples, where it was transmitted by women to the Italians and French of the army of King Charles VIII. 2. Another witness whose testimony has weight is Rodrigo Diaz, who states that the epidemic appeared in Barcelona the year that the companions of Columbus returned from their first voyage. 3. The testimony of numerous Italian writers of the sixteenth century, among them Benedetti, Cunano, Gibini, Leoniceno, Montagnana, Torelli, Benivieni, Vigo, Mattioli, Fracastoro, Brassavola, Fallopio, not to mention others, who all proclaim the modern origin of the disease. Hence, it is, according to Barduzzi, impossible to deny the evident relationship existing between the appearance of syphilis in Europe, and especially in Italy, in 1493, and the return of the Portuguese boats of Columbus. Contrary to Sudhoff's and Sigerist's conclusions—both being believers in the ancient origin of syphilis in Europe—Barduzzi maintains that this opinion is not built upon a solid basis and offers no really serious proof that the disease existed either in antiquity or the medieval epoch before 1493.

Of great historical interest is the recent work of

K. Dohi, of Tokio, who has studied the historical aspects of syphilis in Europe and in the Orient—India, China and Japan—as well as the ancient medical literature of these countries. Leaving aside Dohi's remarks on the origin of European syphilis which are based on Procksch's and Bloch's writings—the earlier important writings of Professor Rollet, of Lyons, being probably unknown to Dohi since he does not refer to them—we would briefly consider what the Japanese writer has to say in respect of the discoveries and opinions emitted on the socalled syphilitic changes observed in skeletons belonging to the stone age. He refers to Adachi's discoveries of Japanese skulls and tibias belonging to this period, but with Minami and others, it must be admitted that these skeletal specimens are not convincing.

Dohi carefully studies the ancient Chinese physicians of the precolumbian period and refers to some more or less singular texts relating to leprosy, genital ulcers—perhaps ulcus molle, etc. Ancient Japanese medical literature is not more explicit and a manuscript studied by Scheub and Kayama—upon which much hope was founded—has proved not to be authentic. The same applies to India. In this country the word for syphilis is *phisango,* and this does not occur in any text prior to 1495. Here again, all proof is lacking that syphilis existed in the Orient before the return of the crews of Columbus from America to Spain.

There would seem to be some evidence that syphilis developed in India after 1498, with the crews of Vasco de Gama's fleet. In China it was just described by physicians about 1520. The disease probably was introduced via Canton before the arrival of the Portuguese in China, probably by that intermediary of Chinese coming from India or the Malaysia islands. Syphilis appears to have invaded Japan before 1543, by the intermediary of Japanese pirates who ravaged Malaysia seas and coasts of China, or by the inhabitants of the Lioukiou archipelago. But syphilis developed in Japan before the Portuguese came there.

Dohi also gives a good summary of the writings of the Chinese and Japanese physicians of the sixteenth century and shows that they were familiar with hereditary syphilis, not to mention the ordinary manifestations of the disease. The Japanese physicians belonging to the Chinese school, as well as those belonging to other schools, have left us many descriptions of syphilis, in many respects quite as exact as those given by European physicians of the epoch.

Antiquity of Syphilis.—It is generally stated that syphilis was imported in 1495 or 1496 by the sailors of Christopher Columbus on their return from Spain. Certain authors, however, within the last twenty years have opposed, with the aid of authoritative arguments, this opinion of the American origin of syphilis, which did not appear until a generation later, about 1535, and which they consider based upon faulty testimony, for commercial motives. In a communication that he made to the Congress of Medicine at London in 1913, Sudhoff declared himself to be a firm believer in the antiquity of the disease. *La France Médicale* has summarized as follows this learned communication:

In recent times, and also toward the close of the Middle Ages, prehistoric bone fragments were discovered apparently showing syphilitic lesions. But all the while certain experienced scientists, such as Lannelongue and Gangolphe, were not altogether convinced. Moreover, it is strange that only those bones found in the American tombs of the seventeenth and eighteenth centuries presented syphilitic lesions. This leads us to believe that it may have been the Europeans who carried syphilis to America. The troops of Charles VIII, perfectly disciplined, never gave themselves to any excesses and it is probable that the epidemic with which they were smitten was an epidemic of typhus. In all the socalled syphilized regions one recognizes the long existence of the disease; the popular speech, the municipal edicts, the therapeutic measures prove it. It was the malady of *mauvais boutons* treated as today by rubbing with mercurial ointment. It was already established in the works of the alchemists of the twelfth century that mercurial ointment was the treatment, and the manner of applying it, its therapeutic action and its special results such as salivation are described. The use of the mercurial rubbing enables us to distinguish leprosy from eczema and from syphilis, a constitutional disease. The Italian physicians of the twelfth and thirteenth centuries had begun to take up the problem, and in the thirteenth and fourteenth had communicated the results of their labors to their colleagues in the south of France. The alchemical medicine of Arnaud de Villeneuve bears witness to this.

It was known even in the fourteenth century that the sexual act was the usual avenue to syphilis, the *gros mal* of the courtesans of the south of France. The Italians, rendered furious by the invasion of Charles VIII, translated *gros mal* as *mal franzoso,* as an expression of their anger. The expression spread like wildfire. In Germany the disease came to be known as *Franzosenkrankheit,* French disease, and in certain cities free treatment was given sufferers in places known as *maisons françaises* by the people. This expression of *mal français* constitutes, according to Professor Sudhoff, a title of glory for the science of medicine in the south of France, which tore the veil away from the face of this insidious disease and taught the earliest prophylaxis and cure. —Translated from *Æsculape.*

The Earliest Medical Journals.—Dr. Leartus Connor states (*J. A. M. A.,* June 14, 1884) that the first medical journal was a Paris publication edited by Nicholas de Blegny. It appeared in 1679. The first medical journal published in this country was apparently a translation of the *Journal de Médecine Militaire* issued in Paris from 1782-88. It appeared in New York City in 1790. The first really American medical journal was a quarterly, *The Medical Repository,* published in New York from 1797-1824. The second American journal, the *Philadelphia Medical Museum,* was born in 1804 and lived only seven years. The *Baltimore Medical and Physical Recorder* was the third American journal, issued from 1808-09. Boston's first medical journal was the *New England Journal of Medicine and Surgery,* 1812-27. This quarterly was consolidated in 1828 with the *Boston Medical Intelligencer* to form the *Boston Medical and Surgical Journal,* still being published.

Editorial Articles

WHOLE MILK IN INFANT FEEDING

In infant feeding, as in the diet of adults, the object of modern medicine is to establish a form of diet which conforms most closely to that which is natural; in short, to work out a means of nutrition based on scientific principles. But again, as is the case with the food of adults, it is a difficult matter to lay down a diet table for infants which is at one and the same time scientific and nutritious.

For some time a discussion has been going on between the advocates of modified milk and whole milk for infants. Not long ago milk, modified in accordance with the results of laboratory experiments, was regarded, when mother's milk was not available, as the proper food for babies. More recently, however, a certain amount of scepticism seems to have arisen with respect to the advantages of modified milk, and it is being urged by some authorities that whole milk is better adapted for infant's consumption. Dr. Leonard Findlay, of Glasgow, is one of the leading supporters of this viewpoint and at a meeting of the Section for the Study of Disease in Children of the Royal Society of Medicine, London, on April 24, 1925, argued his case strongly.

In the first place he admitted the necessity for boiling milk owing to the fact that in Great Britain it was impossible to obtain a perfectly pure supply. He insisted that it was idle to attempt so to modify cow's milk that it resembled human milk in all its most valuable essentials, and pointed out that dilution of cow's milk opened up the danger that certain aminoacids, for instance, might be so reduced in quantity as to give rise to disturbances in growth, just as the dilution frequently practised so reduced the iron intake of an infant as to produce anemia. Dr. Findlay pays little heed to the argument that an infant is unable to digest whole milk, as certain metabolism experiments on marasmic infants had shown that such babies had no difficulty in dealing with cow's milk. Judging from his clinical experience a majority of children digested and thrived on whole cow's milk, excluding those in whom definite infections of the digestive tract were present. Findlay concluded that the differences between cow's milk and human milk were of so subtle and fundamental a character that it was futile to attempt to humanize cow's milk in such a manner that it constituted an efficient substitute. In his opinion, boiled whole milk gave better results than any form of modification in all save in the very youngest infants.

Dr. Hugh Thursfield supported the employment of boiled whole milk in infant feeding on purely clinical grounds. Dr. Eric Pritchard of London opened the case for the modification of cow's milk and based his contention upon the incontrovertible argument that except in a comparatively few instances breast milk is the best food for infants and failing this in his opinion the most efficient substitute was that which approximated in composition as closely as possible to breast milk. Moreover, Dr. Pritchard and Dr. Tewesbury pointed out that not only were best results to be expected from such a modification, but had been obtained at their hands.

Dr. Pritchard held that the problem was not the simple one of dealing with the protein, fat and carbohydrate so as to obtain these three elements in correct proportion, but the much more complicated one of adjusting the relative proportions of all the thirty different elements of milk, each of which played some part in metabolism. He laid most stress on the harmful effects of the excess protein contained in cow's milk which, in his opinion, was dangerous both for its immediate effects in leading to fermentation and the absorption of the toxic products of this process, and also for its remote effects, such as those produced in the liver and kidneys by the extra burden thrown upon them and those taking place in that "long suffering organ, the stomach," by the excessive acid production necessary for the digestion of cow's milk. Dr. Tewesbury also inveighed against the use of whole milk on account of its high protein content, stating that according to his view, the signs of indigestion manifested so frequently in infants were due to too much protein. In support of the good effects of modified milk he drew attention to the excellent results obtained by the simple modification of cow's milk along the lines introduced by Sir F. Truby King.

The outcome of this discussion tends to emphasize the need for breast feeding whenever available. There is no form of food for infants which is an absolutely efficient substitute for human milk. On the other hand, it must be taken into consideration that a substitute as good as possible must be found as so many mothers at the present time are either unable or unwilling to feed their babies themselves. While a large number of men of experience assume that boiled milk is as satisfactory a food for healthy babies as any artificial food, it must not be forgotten that in the large cities of today a large number of babies are not healthy and these must be dieted in the most effective way. And again the per-

sonal equation of the infant must be taken into account and, as Dr. H. C. Cameron remarked at the London meeting, artificial feeding is in the nature of "sighting shots" and the object of the physician should be to discover the best sighting shot. The arguments of Dr. Pritchard and Dr. Tewesbury that whole milk on account of its excess protein is likely to cause restlessness, sleeplessness, constipation, colic and flatulence cannot but carry weight.

This country may be termed virtually the home of modified milk feeding of infants and it would be instructive to learn the views of authorities here as to the respective merits of whole and modified milk for infant feeding.

LOSS OF HEAT AND WEIGHT IN NEWBORN BABIES

Papers or records of observations on newborn infants are comparatively rare in current medical literature, a neglect which is to be deplored as valuable facts may be gathered from a close investigation of a child shortly after birth. However, the care of the infant from every point of view is now receiving some of the attention which its importance deserves and useful knowledge is being accumulated. At a meeting of the Section of Obstetrics and Gynecology of the Royal Society of Medicine held in London on December 4, 1924, Professor Louise McIlroy read a paper on some observations upon the relationship between the loss of heat and loss of weight in the newborn. It was pointed out that the usual explanations that changes in the metabolism of the infant when adapting itself to neonatal conditions do not seem sufficient to explain the loss of weight in all cases. A series of observations were made upon infants who were wrapped in a warm blanket at birth, and subsequently cleansed daily with olive oil instead of soap and water.

The results were extremely satisfactory; there was less initial loss of weight in the first three days than in the controls or bathed babies, and the increase of weight was more appreciable during the rest of the infant's stay in hospital. The controls were taken at the same season of the year, same birth weights, and the same number in the family. Charts of temperature taken by rectum at birth, one to two hours after and after oiling were given and a drop of one to two degrees was found to be present in the majority of cases. Exposure to air during cleansing was shown to cause a loss of heat.

Professor McIlroy insisted that newborn babies should be kept as much as possible in one apartment with an even temperature, and bathing should be dispensed with for seven or eight days after birth. The infants are sweet and clean after oil has been used as it is wiped off after the daily cleansing. In the treatment of infants suffering from shock at birth according to McIlroy it was found that better results are obtained by warmth and rest and the avoidance of baths or artificial respiration.

The respiratory passages should be cleared of mucus by a rubber tube and stimulants given, such as pituitrin two minims hypodermically, or strychnine. Gentle massage of the heart is sometimes helpful.

Infant mortality during the first year of life, although it has been decreased considerably by means of the intelligent care of the mother during pregnancy, and the more scientific care of the child immediately and soon after birth, is still higher by far than it should be. Among the poorer classes scientific material and infant care are greatly lacking and in the saving of infant life there is scope for much progress. It is encouraging to know that Professor McIlroy and teachers of her type are alive to the exigencies of the situation and are striving successfully for reform in this direction.

PERAMBULATING OIL TANKS

"As a fat body is more subject to disease, so are rich men to absurdities and fooleries." So wrote Robert Burton three centuries ago, though we seem to be just learning that superfluous collections of body grease are not conducive either to health or longevity. Burton might have played upon the second of his phrases and pointed out the absurdity and foolery of making unnecessary additions to wealth of body weight.

Just what body weight should be is an unanswered question and often an important one for the physician. After a wild search for standards of nutrition in children in which a score or more have been given a thorough trial, it has been at least proved that there is no hard and fast rule, unless it be that of steady and proportionate gain in height and weight under conditions which are known to favor normal growth.

Hunger in healthy children is a thoroughly normal and harmless thing except where they have access to those unnatural man made foods consisting chiefly of sugar. Hunger is, however, something rare in the civilized adult, but is replaced by the æsthetic business of eating for pleasure. One of three things usually results; either excess food is stored up; the tissues are bathed with unusable materials of all sorts; or there is indigestion. Of the three it is hard to say which is worst for the organism.

Beyond middle life there are no standards whatsoever for body weight. The usual weight for height in the previous decade of more active life, when the person believed himself in best health, might seem a safe guide. However, women especially at this

time tend to lay on extra weight. Is a certain amount of this normal, or is it all the result of the continued enjoyment of the table with a diminished bodily metabolism connected with changed sexual characteristics? How far can weight reduction in such persons go and not be harmful?

Feeding is such an important business in life for most people that their feelings as to their condition for work and for enjoyment of life are likely to be tinged by, and subordinated to, their relish for good food. Of course, if this enjoyment of superfluous food has become the end and aim of life, there is no other subjective test of health and the use of the scales as a rough guide is a last resort.

To the operations which have been suggested for prolonging life or rejuvenating it we would like to suggest that a Pawlow fistula might be much more useful for many persons than the substitution of new glands for old or the removal of the large intestine. The proud possessor of an alimentary canal with a trapdoor at the proper location could then devote his energies much more devotedly to feeding and would be saved additional years of life by avoiding diabetes and the other ills that seem attendant on corpulency.

MOST RECENT VIEWS OF SCARLET FEVER

Klein in 1887 was the first to suggest that scarlet fever is of a streptococcal origin. Since which time there has been a tendency to discredit this suggestion and to consider that streptococci are merely secondary invaders, arguing that streptococci are not found in the blood during the early stage even in toxic cases which represent the purest form of the disease. Consequently the improvement sometimes following the use of antistreptococcic serum was ascribed to its action on a secondary infection.

The recent work of G. F. and G. H. Dick tends to confirm the views of Klein in that their investigations point to the conclusion that scarlet fever is a local infection of the throat caused by a particular type of Streptococcus hemolyticus capable of producing a soluble toxin, absorption of which causes the usual manifestations of the disease. The Dicks have devised a test, termed the Dick test, by means of which they assert that the susceptibility of the subject to scarlet fever may be determined. The Dicks' observations have been confirmed by Zingher, Dochez and Blake, Trask and Lynch and treatment along these lines has been instituted. The Dicks have prepared a toxin for active immunization to the disease as well as a scarlatinal antitoxin, while Dochez has prepared an antiscarlatinal serum.

Naturally, there has arisen a demand for these new biological agents and in the *Boston Medical and Surgical Journal,* January 8, 1925, is a communication from Eugene R. Kelley, Commissioner of Health for Massachusetts, discussing the question and issuing a statement of his department's policy with regard to this subject.

While acknowledging the inestimable value of the investigations of Dochez and the Dicks, and while fully realizing that if by further investigations the results reached by them are substantiated they may prove to be the means for controlling scarlet fever, Eugene R. Kelley and his colleagues feel that these measures are still in the investigative stage and should be so held for some time. It is argued by them that from a theoretical point of view further confirmation is needed of the specific etiological rôle of streptococci in scarlet fever. From both theoretical and practical viewpoints further evidence is needed that the socalled toxin produced by scarlatinal streptococci is the specific poison of scarlet fever, that Dicks' toxin produces active immunity to the disease and that the Dick antitoxin and the antiscarlatinal serum of Dochez are agents of curative value. It is pointed out that the available reports on the use of these procedures and agents, promising as they appear to be, are still meagre. Until further confirmation of the accuracy and dependability of the test is forthcoming and until the moot points with regard to the toxin injections and serums have been more fully elucidated and the preparation of these products has been standardized by Federal regulation, the Massachusetts Department of Health feel that the time has not come to make definite statements on the subject or to take part in popularizing the use of the test or the protective and antiscarlatinal agents mentioned above. In this connection allusion may be made to the work of Di Cristina of Palermo and Caronia of Rome, who state that they have obtained cultures of anaerobic organisms in the shape of minute diplococci from the blood, bone marrow, spleen, nasopharyngeal secretion, cerebrospinal fluid and urine during the eruptive period and early stage of desquamation and which they state are the causal agents of scarlet fever.

It may be said that as far as the Dicks' test is concerned that the results are encouraging, but as regards the method of active immunization by subcutaneous injection of a small amount of the toxic filtrate of the variety of Streptococcus hemolyticus that causes scarlet fever, it may be premised that further investigations are needed to show the duration of the immunity conferred. Perhaps it would not be too much to say that the specific immunization to scarlet fever is as yet largely in the experimental stage. Attention may be drawn to the fact that the treatment of malignant and septic cases by intramuscular injection of whole blood or serum

was carried out several years ago on a limited scale by Zingher and more recently by Weaver, with encouraging results. It is gratifying to note that in the efforts to run to earth the causative organism of scarlet fever American investigators have been in the van and it really seems that the solution and effective immunization and antibacterial treatment will take place in the near future. It is best, perhaps, not to prejudice the chances of a complete victory by premature action.

DAILY DOZENS

The comparatively early demise of the author or namer of a set of daily exercises may not be in the least significant that those exercises are not beneficial, but it does signify that it takes something more than muscular exercise to keep one in health and to prolong life.

Muscular activity was evolved for the end of getting us about for the purpose of securing food and escaping other seekers after food of a carnivorous inclination. Of late its chief purpose would seem to be the diametrically opposite business of getting rid of excess food which we have stored up in the way of fat. If not to this end, it is supposed to answer in every other way as a promoter of well being.

These sets of prescribed exercises are practically identical, for there are no new bodily movements under the sun, though the name on the prescription makes them seem new and different. There may be considerable difference, however, in how they are done, and it is this feature that each new adviser of such exercises emphasizes.

Exercise is one of the means of maintaining the body in health, but it is only one of the means and it is far from being primary. As John Burroughs said, "We should not forget that we are built about a gut," and, practically, we do not forget this, for the end and aim of most people is centred about catering to this gut. Unfortunately they cater to it entirely beyond its desires or deserts, and, in consequence, they try to make up for this excess by going in for muscular exercise. The futility of this is well illustrated by fact that the daily dozen of popular exercises uses up, according to a laboratory investigation, only so much energy as is contained in a small lump of sugar, while it is likely to create an appetite for many such lumps.

The appeal to exercise as the chief or only source of health is not confined to the individual. Dr. John Sundwall has vigorously pointed out that "One of our outstanding delusions is that which proclaims play, which is so often overstimulated, and competitive athletics, which are so often overtaxing, as constructive health measures. An example of this widespread and dominating phantasm is seen in the following incident. After the World War, owing to the astoundingly poor showing of our draftees in the physical examinations . . . a conference was called at Washington by the Secretary of War, the Secretary of the Navy, the Commissioner of Education, etc., for the purpose of initiating measures whereby the physical regeneration of America would be accomplished. The result was the organization of another athletic association." In fact, physical education has been proclaimed by a host of advocates as the cureall for the various defects of present day man.

Unfortunately, many of these well meaning persons see in physical education only exercise and not the wise use of all the means of bringing about health beginning with the prenatal history of the child.

THE CAUSE OF CANCER

The announcement in the *Lancet*, July 15, 1925, that the cancer germ has been isolated has aroused intense interest in medical and scientific circles and has inspired the hope in the members of the community at large that the conquest of the disease may be in sight at last.

The workers who have perhaps achieved this triumph are Dr. William E. Gye and J. E. Barnard, F.R.S., of the English National Institute of Medical Research. Dr. Gye, Mr. Barnard and coworkers it is said have been able to isolate an organism from that type of cancer known as chicken sarcoma, completing the brilliant research work of Dr. Peyton Rous in the Rockefeller Institute, New York. One of the outstanding features of the series of investigations in London is that the discovery was rendered possible only by the use of what is termed the ultramicroscope devised or improved by Mr. J. E. Barnard, a layman.

The germ isolated is a filterable virus of the poliomyelitis and foot and mouth disease type. As the *Lancet* pointed out, this improved microscope opens a field of almost illimitable possibilities as far as the discovery of disease is concerned. Minute viruses are the causes, or are exciting causes of many maladies. However, it would be premature to enter into a discussion of the subject until more details are known.

In the meantime, it may be said that undoubtedly a step in advance has been made. If Dr. Gye's results are confirmed by independent workers, and it is proved that cancer is caused by a germ, it will be not only a discovery of the first importance, but can be put into practical effect in the prevention of the disease.

BRITISH CONGRESS OF OBSTETRICS AND GYNECOLOGY

Among those present were Professor J. Whitridge Williams, of Baltimore, who opened the general discussion. Professor Williams said that it was now the universal belief that puerperal sepsis was a contact infection, and it would be a misfortune if that view were abandoned. He had taught for a long time that the worst thing that could be done was to interfere with the interior of an infected woman's uterus. When one encountered a severe case of puerperal infection, antistreptococcus serum seemed to be of no avail. Therefore, all that could be done was to try to find some means of combating it.

Two thirds of the patients with the thrombophlebitic form of pyemia would die if left alone, and if operated on they would probably all die. The less severe cases which did not come into these categories would recover if left alone, because the outcome depended on the degree of resistance of the patient and on the violence of the causative bacteria. Vigorous measures applied to these milder forms might convert a condition which was likely to recover into one which might be fatal. There was need for research, not purely obstetrical, but along the general lines of bacteriotoxic methods. The general sense of the meeting was that the hope of combating successful puerperal sepsis lay in preventive measures, such as the provision of better housing, antenatal care and so on.

Dr. T. Watts Eden pointed out that the profession had scarcely yet begun the systematic study of puerperal infection; it had not even settled whether, for the most part, the infection was intrinsic or extrinsic. Nor was the real significance of streptococci in the vagina known. Until hospitals provided special accommodation for puerperal sepsis cases, so that they could be investigated from beginning to end, there would not be much progress in the matter. There must first be real assistance from the government. On the suggestion of Dr. Fletcher Shaw, he proposed that a memorial be sent from the Congress to the Ministry of Health, urging the provision of hospital accommodation for the care and investigation of these cases.

INDUSTRIAL MORBIDITY STATISTICS

Since the problem of industrial morbidity is of the greatest interest and importance to industrial management, to physicians engaged in industrial work, to statisticians and to insurance companies, the statistics of industrial morbidity, and their extent and relationship to the industrial life of the world, have held the attention of investigators for the past several years. Some of these investigations have shown that few attempts are made by industrial medical departments to keep statistics of their morbidity experience, and that those that are kept have no common basis for comparison. The lack of adequate knowledge of the problem was further intensified by the efforts of different organizations to find some measure for it, but without success.

In order to stimulate cooperative interest in this work and to bring about some definite action on the matter, the National Industrial Conference Board invited a group of physicians and statisticians who were representative of organizations interested and who were themselves interested in the subject, to meet and consider the problem. At its first meeting this committee discussed the need for a standardized classification of industrial morbidity brief enough to commend it to busy industrial medical departments, but sufficiently comprehensive to provide proper measure of sickness experience in industry. It was felt that none of the classifications already devised by individual plants met the needs of all plants, and it was decided that a classification should be developed based on the International List of Causes of Death, third revision.

A technical subcommittee made up of expert statisticians was appointed to prepare an abridged classification. This was presented later to the committee as a whole and adopted. It was felt that the work of the committee should be placed under the sponsorship of some interested organization that could supply a permanent centre from which the work could be distributed. This the U. S. Public Health Service agreed to do.

The committee feels that it has made at least a beginning upon a work of great importance both to industry and to the community at large. If this classification which it has devised is carefully used in recording sickness experience, it will give a fair indication of the extent of disability from sickness in any given industry.

HEALTH OF CHILDREN IN INDUSTRY

Of 922 defects recorded in 412 children under sixteen regularly employed, 260, or twenty-eight per cent., were considered to accentuated by some condition of the occupation, according to a recent issue of the *Bulletin* of the New York State Department of Labor. Approximately one fifth of the children had serious visual defects, and only a seventh of these cases had been adequately corrected with glasses. Dental defects requiring immediate treatment were found in approximately one third, and 12.8 per cent. had hypertrophied tonsils, four per cent. heart affections, one per cent. symptoms suggestive of early tuberculosis, approximately one fourth had flatfoot to some extent, and only forty-five per cent. had normal posture.

Of the 412 children examined, only eighteen had no physical defects, ninety-nine had minor defects requiring hygienic regulation and diet, 179 had moderate defects requiring minor medical attention, ninety-three had more serious conditions causing temporary or partial incapacity but capable of cure by proper treatment, sixteen had organic diseases or physical impairment capable of mitigation, and seven had such serious organic lesions as to require immediate treatment and probable cessation from work.

The Physicians' Home—The First Medical Hearthstone in America

In Caneadea, New York, at an altitude of two thousand feet, far above the scenes of turmoil, we find the first unit of the Physicians' Home. The Physicians' Home is an institution, the ideal of which is to render service to those who through the years have been faithful to a suffering, though sometimes unappreciative public.

The scope of the institution is national and as it grows it will care for old and infirm members of the medical profession of any recognized school of medicine of any state. Their wives and widows also will be accepted as guests, and everything possible is done to preserve the home atmosphere.

The staff of the home is headed by a matron who serves the guests with the same spirit of love and fidelity that we find in a mother for her children. There is no institutional atmosphere about this home. It is a real home for physicians and surgeons who have been honorable in their conduct and yet have fallen victims to the common foes, poverty or broken health.

PHYSICIANS' HOME, CANEADEA, N. Y.

The home is near the banks of the Genesee River in Central Western New York and is surrounded by an area noted for its scenic beauty. It consists of a fertile farm of one hundred and eighty-six acres, the gift of Dr. Stephen V. Mountain, of Olean, N. Y., as a memorial to his father.

The home is sponsored by and has the unanimous endorsement of the American Medical Association and the New York State Medical Society. It is under the jurisdiction of the New York State Board of Charities, from which it derives its charter. It is officered by such well known men as Robert T. Morris, Silas F. Hallock, Ralph Waldo, Warren Coleman, Max Einhorn, Albert G. Weed, W. Freudenthal, Richard J. Kevin and others. It derives support from the voluntary contributions of the medical profession of the United States and kindly disposed laymen who are interested.

There are well filled barns and silos which provide food for a herd of thirty-five Holstein cattle and two hundred fowl. Pure water is piped directly from the mountain springs in the near vicinity. The house is a commodious structure of twenty-eight rooms, modern in every sense, having its own electric lighting plant, steam heating system, modern plumbing facilities on all floors; it is well and comfortably furnished and has two assembly rooms in which are a piano, victrolas, and the ever popular radio.

The physical welfare of its guests is met by well ventilated bedrooms and baths, running hot and cold water, two large airy drawing rooms and verandas. The home even maintains a medical clinic under the supervision of a competent physician. One who expects to find the usual institutional atmosphere with rules and regulations, restrictions and the like, will be agreeably surprised to find them conspicuous by their absence. Instead you will find a well regulated, contented family of intellectual men and women whose only restrictions are a selfimposed regard for the comfort of each other shown in the spirit of helpfulness that amounts almost to rivalry.

There you will find good old fashioned meals, with plenty of fresh milk and eggs. One may ramble over beautiful meadows and woodland and visit the inland lakes and forests. There are fishing and hunting. The State park is nearby where the chiefs of the Six Nations once held their council seat.

The open hospitality of the place is apparent. You are cordially invited to visit the institution, and the men and women who are there will be glad to see you and when you go away you will be carrying with you the message of one of the most worthy charitable works being done by the medical profession in this country.

The guests at the Physicians' Home might be thoughtlessly and carelessly called failures, but they are not failures; they are successes. They are the men and women in the profession who were in honorable standing but who have met the reverses which so often leave them dependent upon others. No one can measure how much these men and women have contributed to humanity—the broken men and women with crushed hopes, who never reached the goal.

George Fillmore Swain, professor of engineering at Harvard, tells his young men that "the young engineer may always learn more from the study of failures than from the study of successes."

And so we find these men and women have contributed to human progress and their contribution should not be overlooked—neither should their welfare be neglected. You can not take the old family doctor, the stouthearted old surgeon, or the palsied professor and throw him into the discard—the almshouse. Such action would make perhaps the most pitiful picture in life—that of a man who has outlived his friends and relatives and for whom no one cares.

There is no place like or similar to this home where they can go and feel that they are not dependent. Here they are in their own homes, main-

tained by their fellow physicians and surrounded by men of the same intellectual and mental achievement.

The Physicians' Home has taken care of upwards of thirty of such men and applications are continually being made to have the service increased. It is evident from what has been said that the Physicians' Home has been a successful project up to and within the means thus far available. It will be obvious to you that much remains to be accomplished. We must not fail. The duty is yours and ours. The need is urgent.

Any person is eligible to a contributing membership which costs but $10.00 per year—$100.00 constituting a sustaining membership, paid but once. Many will hear and heed this call from a motive of philanthropy. Others will not be unmindful of the possible protection vouchsafed their wives and widows or themselves when considered in the light of insurance against a possible adverse turn of the wheel of fortune.

Please stop a moment, doctor, and think this over, for if every physician in this country were to know what the officers of the Physicians' Home know, this institution would have their support promptly and not only for this home but for other units of the home in different parts of the United States.

We ask you to do two things. Assist your county society to complete a successful organization for the support of the home, and send your check for as generous an amount as your heart and ability may dictate.

It is requested that physicians remember this practical and altruistic charity in their testamentary devices and it is also suggested that they lay it before their friends and patients.

All communications should be made to Silas F. Hallock, M.D., 901 Lexington Avenue, New York city, Secretary of the Board.

News Items.

Infantile Paralysis Epidemic.—Health authorities in Jersey City, New Jersey, express alarm over the prevalence of infantile paralysis in the city during the last few weeks. Seven infants are now in the contagious disease hospital, the largest number since 1916.

Smallpox in Chicago.—Dr. Herman N. Bundesen, commissioner of health of Chicago, has announced that the smallpox situation there is more serious than at any time since 1905, and has asked for an appropriation of $25,000 for combating the disease.

Fellowships in Plastic Surgery.—The General Education Board has provided funds for two fellowships in plastic surgery, each of three years' tenure, at Johns Hopkins Hospital. The fellowships are open to doctors of medicine and provide for research and laboratory work.

Postgraduate Courses in Gastroenterology at Columbia.—The second section of the courses in gastroenterology, which are being given at Columbia by Dr. John L. Kantor will be held from August 3d to 21st, for the preliminary work, and from August 22d to September 2d, for the practical course. Application should be made to the Dean of the School of Medicine.

Wayside Eating Establishments.—Dr. Matthias Nicoll, Jr., commissioner of health of New York State, has made an appeal to health officers of towns and villages in whose jurisdiction are located wayside eating places and rest rooms patronized by automobile parties, to inspect sanitary conditions at frequent intervals. The state department has received many reports of bad sanitary conditions in such places, but does not feel it can itself carry on such inspections.

International Child Welfare Congress.—A conference to discuss problems of child welfare will be held in Geneva, August 24th to 28th, under the auspices of the Swiss Government.

International Postgraduate Courses in Berlin.—The Faculty of Medicine of Berlin University announce several postgraduate courses beginning in October, one of them being for oculists. Details may be obtained from International Postgraduate Courses, Luisenplatz 2-4, Berlin NW6.

New Veterans' Bureau Hospital.—A tract of five hundred acres of land near Northport, Long Island, has been acquired by the U. S. Government, on which will be built a thousand bed hospital for psychiatric patients of the New York district. The cost is estimated at between two and three million dollars.

Civil Service Examinations.—Examinations for entrance into the regular corps of the U. S. Public Health Service will be held September 14th, at Washington, Chicago, New Orleans and San Francisco. Candidates must be medical graduates. Information may be obtained from the Surgeon General, U. S. Public Health Service, Washington, D. C.

Prize Thesis in Surgery.—A prize for a thesis in surgery, to be awarded every other year at the University of Virginia, has been established by Dr. John Shelton Horsley, of Richmond. The prize amounts to about one thousand dollars, and graduates of the medical department of the university, of not more than fifteen years' standing, are eligible. The first award is next June, and theses should be addressed to the dean not later than February first.

Relics for New York University.—In memory of Dr. Frank Ridgway, her father, Miss Sally Ridgway has presented to New York University a flag used as a marker to direct people to hospital tents at the battles of Gettysburg, Chancellorsville, and Spottsylvania, and a case of surgical instruments used in those battles. Doctor Ridgway was a student at the University at the time of the Civil War, but left to volunteer for service.

Personal.—Dr. Dean Lewis, of Chicago, has accepted the chair of surgery at Johns Hopkins University Medical School. A banquet in his honor was recently held in Chicago.

Dr. Robert T. Miller, of Johns Hopkins University, Dr. George C. Sears, of Harvard University, and Dr. Edwin St. J. Ward, of the American University, Beirut, have been honored by the degree of doctors of science, by Amherst College.

Dr. Samuel J. Crumbine, formerly dean of the Kansas School of Medicine, has been appointed general director of the American Child Health Association.

Dr. Lewis J. Friedman has moved his office to 315 East Eighteenth Street, New York.

Dr. Henry F. Mace of Walton, New York, has been appointed assistant medical inspector for rural schools, of the state department of education. He succeeds Dr. Willard T. Rivenburg, who recently resigned.

Dr. Hubert Work, secretary of the interior, and former president of the American Medical Association, has received the degree of doctor of laws from the University of Colorado.

Dr. John S. Davis, of Johns Hopkins Hospital, has received the honorary degree of Master of Arts at Yale.

Dr. Charles N. Meader, dean of the University of Colorado School of Medicine, has resigned to enter private practice; he will, however, continue as dean emeritus, and head of the department of medicine. Dr. Maurice H. Rees, assistant dean, has been appointed to the vacancy.

Dr. and Mrs. Homer H. Wheeler, of Indianapolis, have donated a large plot of ground to the city for a park.

Prof. Albert A. Michelson, head of the department of physics of the University of Chicago, has been appointed to the first of the Distinguished Service Fellowships established by a fund given by Martin A. Ryerson, donor of the Ryerson Physical Laboratory.

Dr. Walter E. Garrey of Tulane University Medical School is to hold the chair of physiology at Vanderbilt University, Nashville, beginning in the fall.

Dr. David E. Hoag, of New York, a regularly commissioned officer in the Medical Reserve Corps, U. S. Army, who was ordered to active duty, by the War Department, for a period of intensive training, and who has been serving with the 245th Coast Artillery, stationed at Fort Wright, Fisher's Island. N. Y., has returned to New York and resumed his practice.

Endowment for Johns Hopkins.—An endowment of $1,500,000 for the Johns Hopkins' Children's Fund will be sought for beginning in the fall. The fund is for the care of sick and needy children of Baltimore. Part of the $80,000 a year devoted to the care of needy children by the Hospital, has come from a gift of $700,000 from the General Educational Board, which, however, must be used as a building fund and will no longer be available.

Rockefeller Institute Appointments:—The Board of Scientific Directors of The Rockefeller Institute for Medical Research announces the following appointments and promotions:

New Appointments: *Members,* Dr. Winthrop J. V. Osterhout and Dr. Florence R. Sabin.

Associates, Dr. Robert T. Hance, Dr. Marian Irwin. *Assistants,* Dr. Lawrence W. Bass, Dr. William W. Beattie, Dr. Francis H. Case, Mr. William C. Cooper, Jr., Dr. Charles A. Doan, Dr. Philip Finkle, Mr. Earl S. Harris, Dr. Charles H. Hitchcock, Dr. Philip Levine, Dr. Richmond L. Moore, Dr. Ralph S. Muckenfuss, Dr. Richard E. Shope, and Dr. Hans Theiler.

Fellow, Dr. Telémaco S. Battistini.

Promotions: *Fellow to Assistant,* Dr. David Davidson, Dr. Philip Reichert.

Dr. Laura Florence, hitherto an associate in the Department of Animal Pathology, has accepted an appointment as assistant professor of histology and embryology at the New York Homeopathic Medical College and Flower Hospital.

Dr. Stuart Mudd, hitherto an associate in pathology and bacteriology, has accepted an appointment as assistant professor of experimental pathology at the Medical School of the University of Pennsylvania, and as associate in pathology at the Henry Phipps Institute for the Study, Treatment and Prevention of Tuberculosis.

Dr. Christopher H. Andrewes, hitherto an assistant in the Department of the Hospital, has accepted an appointment as assistant to Professor Francis R. Fraser, Medical Unit, St. Bartholomew's Hospital, London, England.

Dr. Douglas Boyd, hitherto an assistant in the Department of the Hospital, has accepted an appointment as assistant resident in surgery at Lakeside Hospital, Western Reserve University, Cleveland, Ohio.

Dr. Arnold M. Collins, hitherto an assistant in Pathology and Bacteriology, has accepted an appointment on the chemical research staff of the E. I. du Pont de Nemours Company, Wilmington, Delaware.

Dr. Robert Elman, hitherto an assistant in pathology and bacteriology, has accepted an appointment as assistant in Surgery, Department of Surgery, Washington University Medical School, St. Louis, Missouri.

Dr. Joseph H. B. Grant, hitherto an assistant in pathology and bacteriology, has accepted an appointment as house officer in pediatrics at Johns Hopkins Hospital.

Dr. C. Philip Miller, Jr., hitherto an assistant in pathology and bacteriology, has accepted an appointment as assistant professor of medicine in the Graduate School of Medicine of the University of Chicago.

Dr. Waro Nakahara, hitherto an assistant in biophysics, has accepted an appointment as associate pathologist at the Government Institute for Infectious Diseases, Tokio Imperial University, and research associate at the Institute of Physical and Chemical Research of Tokio.

Dr. Everett S. Sanderson, hitherto an assistant in the Department of Animal Pathology, has accepted an appointment as assistant professor of bacteriology in the Medical School of the University of Virginia.

Dr. David T. Smith, hitherto an assistant in pathology and bacteriology, has accepted an appointment as pathologist at the New York State Hospital for Incipient Tuberculosis, Ray Brook, New York.

Dr. Elmer L. Straub, hitherto an assistant in pathology and bacteriology, has accepted an appointment as assistant resident pathologist at the University of Louisville, Kentucky.

Dr. Chester M. Van Allen, hitherto an assistant in pathology and bacteriology, has accepted an appointment as assistant professor of surgery in the Graduate School of Medicine of the University of Chicago.

NEW OFFICERS OF STATE SOCIETIES

At the recent annual meetings of the various state medical associations, the following officers were elected:

Connecticut State Medical Society.—Dr. Robert C. White, Willimantic, president; Drs. Ernest R. Kelsey, Winsted, and Charles T. LaMoure, Mansfield Depot, vice-presidents; Dr. Charles W. Comfort, Jr., 27 Elm Street, New Haven, secretary, and Dr. Phineas H. Ingalls, Hartford, treasurer.

Florida Medical Association.—Dr. John S. McEwan, Orlando, president; Drs. Henry Mason Smith, Tampa; Carl A. Williams, St. Petersburg, and John A. Simmons, Miami, vice-presidents, and Dr. Shaler A. Richardson, Jacksonville, secretary-treasurer and editor of the journal.

Medical Association of Georgia.—Dr. Frank K. Boland, Atlanta, president; Drs. William R. Dancy, Savannah, and Henry M. Fullilove, Athens, vice-presidents, and Dr. Allen H. Bunce, Atlanta, secretary-treasurer.

Iowa State Medical Society.—Dr. Smith A. Spilman, Ottumwa, president; Dr. Thomas E. Powers, Clarinda, president-elect; Drs. Frank C. Mehler, New London, and Frederick F. Murray, Cedar Rapids, vice-presidents; Dr. Tom B. Throckmorton, Des Moines, secretary, and Dr. Addison C. Page, Des Moines, treasurer.

Kansas Medical Society.—President, Dr. Francis A. Carmichael, Osawatomie; vice-presidents, Drs. Benjamin F. Morgan, Clay Center; Joseph E. Hawley, Burr Oak, and Francis H. Smith, Goodland; treasurer, Dr. George M. Gray, Kansas City.

Massachusetts Medical Society.—President, Dr. James S. Stone, Boston; vice-president, Dr. Michael F. Fallon, Worcester; secretary, Dr. Walter L. Burrage, Brookline; treasurer, Dr. Arthur K. Stone, Framingham Center; orator, Dr. Charles F. Painter, Newton, and librarian emeritus, Edwin H. Brigham, Wellesley Hills.

Minnesota State Medical Association.—Dr. Herman M. Johnson, Dawson, president; Drs. William F. Braasch, Rochester; Arthur N. Collins, Duluth, and Eugene G. McKeown, Pipestone, vice-presidents; Dr. Edward A. Meyerding, St. Paul, secretary, and Dr. Earle R. Hare, Minneapolis, treasurer.

Mississippi State Medical Association.—Dr. Giles S. Bryan, Amory, president; Drs. Franklin G. Riley, Meridian, and Oscar N. Arrington, Brookhaven, vice-presidents; Dr. Thomas M. Dye, Clarksdale, secretary, and Dr. James M. Buchanan, Meridian, treasurer.

Montana Medical Society.—Dr. Charles F. Watkins, Billings, president; Dr. Fred F. Attix, Lewistown, president-elect; Dr. Ernest D. Hitchcock, Great Falls, vice-president, and Dr. Elmer G. Balsam, secretary-treasurer, re-elected.

New Hampshire Medical Association.—Dr. Thomas W. Luce, Portsmouth, president; Dr. John H. Gleason, Manchester, vice-president, and Dr. Dennis E. Sullivan, Concord, secretary-treasurer. The house of delegates created the new office of corresponding secretary. The next annual meeting will be at Concord.

New Jersey State Medical Society.—Dr. Lucius F. Donohoe, Bayonne, president; Drs. James S. Green, Elizabeth; Walter P. Conaway, Atlantic City, and Ephraim R. Mulford, Burlington, vice-presidents; Dr. Elias J. Marsh, Paterson, treasurer; Dr. John Bennett Morrison, Newark, recording secretary; and Dr. William J. Carington, Atlantic City, corresponding secretary.

New Mexico Medical Society.—Dr. Charles F. Beeson, Roswell, president; Dr. Harry M. Smith, Las Vegas, vice-president, and Dr. Charles M. Yater, Roswell, secretary-treasurer.

Medical Society of the State of New York.—President, Dr. Nathan B. Van Etten, Bronx County; first vice-president, Dr. W. H. Ross, Brentwood, Long Island; second vice-president, Dr. F. H. Flaherty, Syracuse, N. Y.; speaker, Dr. E. E. Harris, New York County; vice-speaker, Dr. G. M. Fisher, Utica, N. Y.; secretary, Dr. Daniel S. Dougherty, New York County; assistant secretary, Dr. H. G. Myers, New York County; treasurer, Dr. C. G. Heyd, New York County; assistant treasurer, Dr. James Pedersen, New York County; editor of the *Journal,* Dr. Orrin S. Wightman, New York County.

Medical Society of the State of North Carolina.—Dr. William DeB. MacNider, Chapel Hill, president, and Dr. Lewis B. McBrayer, Southern Pines, secretary-treasurer.

North Dakota State Medical Association.—Dr. John H. Rindlaub, Fargo, president; Dr. N. Oliver Ramstad, Bismarck, president-elect; Drs. Thomas Mulligan, Grand Forks, and William F. Sihler, Devils Lake, vice-presidents; Dr. Archibald J. McCannel, Minot, secretary, and Dr. William W. Wood, Jamestown, treasurer.

Ohio State Medical Association.—Dr. Leora G. Bowers, Dayton, president-elect; Dr. Clarence D. Selby, Toledo, was installed as president; Dr. Herbert M. Platter, Columbus, re-elected treasurer, and Dr. Sylvester J. Goodman, Columbus, re-elected secretary of the council.

Rhode Island Medical Society.—Dr. Halsey DeWolfe, president; Drs. Herbert G. Partridge, Providence, and Norman M. MacLeod, Newport, vice-presidents; Dr. Jesse E. Mowry, Providence, treasurer, and Dr. James W. Leech, Providence, secretary.

South Dakota State Medical Association.—Dr. William R. Ball, Mitchell, president; Drs. Theodore F. Riggs, Pierre, Silas M. Hohf, Yankton, and Nelson K. Hopkins, Arlington, vice-presidents, and Dr. John F. D. Cook, Langford, secretary-treasurer.

West Virginia State Medical Association.—Dr. James R. Bloss, Huntington, president; Drs. Richard O. Rogers, Bluefield, Henry C. Skaggs, Montgomery, and Delivan A. MacGregor, Wheeling, vice-presidents; Dr. Hugh G. Nicholson, Charleston, treasurer, and Sterrett O. Neale, Charleston, executive secretary.

Book Reviews

AN ANTHOLOGY OF PEDIATRICS

Pediatrics of the Past. An Anthology Compiled and Edited by John Ruhräh, M.D., With a foreword by Fielding H. Garrison, M.D. With Fifty-four Text Illustrations and Eighteen Full Page Plates. New York: Paul B. Hoeber, 1925.

This beautiful piece of work is a contribution to historical medicine as well as to the special field of pediatrics.

In compiling an anthology a great responsibility confronts the author. He must use his judgment in the selection of the outstanding representatives of the field he endeavors to cover and he must carefully select the salient points of their work so they may be briefly yet correctly appraised. Ruhräh has fulfilled these requirements in an admirable fashion. He has intuitively or consciously so balanced his work so as to give a survey of the vast field of the high spots in the development of the literature of pediatrics from antiquity to modern times in a comprehensive single volume. This is a special art; an art of a singular nature; a musician selecting a well balanced program, interpreted in a most masterly way.

We start our pediatric pilgrimage with the venerable Hippocrates and continue through a list of the ancients to the Arabians, stopping for a feast with Metlinger and finding for the first time perhaps that men like Sydenham, Francis Sylvius, Benjamin Rush, and others more famous for other achievements, had made many salient observations in the realm of pediatrics. The early American and English pediatric publications receive special attention.

There is too much ground covered to give even an inkling in this review. As the author indicates the book may be used to augment or rather supplement Garrison's work on the *History of Pediatrics,* but it also is quite admirable on its own and makes interesting reading.

Of importance is the translated *Grundlage* of Meissner appearing for the first time in English which gives a most complete pediatric incunabula. The entire book is carefully printed and the reproductions are excellent.

PEDIATRICS

Practice of Pediatrics. By Charles Gilmore Kerley, M.D., and Gaylord Willis Graves, M.D. Third edition, revised and reset. With 150 illustrations. Philadelphia and London: W. B. Saunders Company, 1924. Pp. 922.

This volume is replete with practical detail and should prove a great help, not only to the general practitioner but to the specialist, and as a quick reference book as well. The subject matter is extremely well presented in appropriate chapters and the reviewer gains the impression that the author is deliberately avoiding hypothetical discussions to recount his own vast personal experience.

In this respect the volume is refreshing in that it is the author's own experience, his own observation and not in any part the views and experiences of other men, as is the case with many books of this kind. We may not always agree with the author, particularly in his well written chapter on infant feeding, in his use of lime water and top milk formulæ, and his theory of the influence on the infant's digestion of the casein in cow's milk, but the presentation with details of formulæ for varying conditions is so thoroughly practical that to the general practitioner at least, who is always ready to receive practical help based on experience, it more than compensates for the difference of opinion that may exist among specialists.

His chapter, with röntgenographic studies, on mechanical defects as a causative factor in gastroenterological disorders of older children, deserves special mention, in that it is a new field of endeavor in infant studies, with great possibilities for therapeutic results.

FROM INFANCY TO CHILDHOOD

From Infancy to Childhood; the Child from Two to Six Years. By Richard M. Smith, M.D. Boston: Atlantic Monthly Press, 1925.

The author tells us in his preface that, since the transition from infancy to childhood is a period of great mental and physical growth, many perplexing problems in the care of the child are presented which require more than native instinct for their solution. In this little book he has indicated some of the rules which will help parents to keep their children well, and aid them in training their minds.

The text of the book is preceded by two pages on colored paper giving a brief list of first aid suggestions. The chapters discuss in sequence: the doctor, mother and nurse; the nursery; physical development; care of the body; clothes; food; daily routine; sickness; and training and education. Height and weight tables for both boys and girls are given and charts for the keeping of records.

The book is purely nontechnical in style and written in an interesting manner. It is a worthy successor to Dr. Smith's former work, *The Baby's First Two Years.*

HEALTH CARE OF THE BABY

The Health Care of the Baby; a Handbook for Mothers and Nurses. By Louis Fischer, M.D. Fifteenth Edition completely Revised. New York and London: Funk & Wagnalls Company, 1925. Illustrated.

The author tells us in his preface that, because such great progress has been made in the management and especially in the feeding of infants, he has completely rewritten and revised every chapter of the new edition of this book. The book is divided into three main divisions of the subject: general hygiene of the infant; feeding; and miscellaneous diseases and emergencies. Under the first heading are discussed prenatal supervision and prenatal hygiene, the nursery, bathing and care of the navel, clothing, weight and growth, proper training, vaccination, dentition, x ray, and transfusion. Under feeding the author takes up the natural method, premature or weak infants, breast feeding, wet nursing, weaning, mixed feeding, artificial feeding, sugar intolerance, hygienic suggestions in bottle feeding, rules for feeding, intestinal indigestion and dyspepsia, feeding very sick infants, feeding during diarrheal periods, substitute foods, proprietary infant foods,

caloric method of feeding, vomiting, colic, hiccup, convulsions, constipation, rickets, scurvy and jaundice. Under miscellaneous diseases and emergencies he discusses fever and temperature, general rules for contagious diseases and fevers, isolation, the socalled diseases of childhood, catarrhal and sensitive children, skin diseases, accidents and emergencies, eye, ear, and mouth, bad habits, worms, night terrors, external applications and the medicine chest. From this list of subject matter it is evident that Dr. Fischer's book treats the various topics in detail and with thoroughness. However, the book is simply written and the illustrations are good and helpful in elucidating the text.

PEDIATRICS

Kinderheilkunde. Von Professor Dr. Hans Rietschel, Würzburg. Lehmanns Medizinische Lehrbücher, Band VIII. Zweite, völlig bearbeitete Auflage des Atlasses u. Grundrisses der Kinderheilkunde von Prof. Dr. R. Hecker u. Prof. Dr. J. Trumpp. Mit 75 Farbigen Abbildungen auf 37 Tafeln ynd lol Textabbildungen. München: J. F. Lehmanns Verlag, 1925. Pp. xi-446.

The author has given us a complete revision of Hecker and Trumpp's *Atlas und Grundriss der Kinderheilkunde*. In it we find the more recent advances in pediatrics of the last decade. It is not intended to serve as a textbook, but rather as a primer for the general practitioner and medical student. Consequently the clinical features of pediatrics and therapy are given special attention. Controversial material is intentionally omitted, as it finds no place in a work of this kind. The book is up to date and concise. Quite a comprehensive glossary of drug therapy and artificial feeding is appended. The illustrations are numerous and well selected. The colored plates are beautiful reproductions taken from actual cases observed in the wards.

THE CARE OF CHILDREN

Feeding, Diet and the General Care of Children. A Book for Mothers and Trained Nurses. By Albert J. Bell, A.B., M.D. Illustrated. Philadelphia: F. A. Davis Company, 1924. Pp. 290.

This is a very useful handbook for mothers and nurses. The text is simple, clear and sensible. The illustrations are from first rate photographs and more of the same quality might be used with advantage. The book may safely be recommended to all who are interested in puericulture.

MALARIA CONTROL

Department of Health Malaria Research Unit, Haifa. Annual Report, 1923. (Maintained by the American Joint Distribution Committee in cooperation with the Government of Palestine.)

This report considers first the malaria control demonstrations, then the permanent drainage work carried out by the unit, or by other agencies with unit supervision, and finally the work of the laboratory. Nine malaria control demonstrations were organized in different parts of the country. The efforts to control malaria were directed almost entirely towards eradication of anopheles mosquitoes, but the fight against the parasites was also employed as an aid in the campaign. The general plan of campaign in any given demonstration area consisted of the following steps: a, a complete survey of the breeding places within a radius of two kilometers or more from the settlements; b, a survey of the parasite and spleen rates, followed by intensive treatment of carriers; c, systematic house to house search for, and destruction of, hibernating mosquitoes, and d, control of mosquito breeding by various devices described. The first three steps were completed during the months of January to March, when there is no mosquito breeding; the actual campaign was started in April with the commencement of anopheles breeding, and continued until the heavy rains in December. Regular quinine prophylaxis was not given anywhere, but quinine was used only as a temporary measure where mosquito control had broken down. The effect of the control measures was a decided decrease in the malaria incidence. The cost of these measures varied in different districts from a minimum of $0.23 to a maximum of $1.55 per capita. Various drainage projects are described.

BIOLOGICAL TABLES

Tabulæ Biologicæ. Ed.: W. Junk. Uner Mitwirkung von 98 Fachgelehrten. Herausgegeben von C. Oppenheimer and L. Pincussen. Band I. Reine and Physiologische Physik, Physikalische Chemie und Biologische Anwendungen. Bearbeitet von Dr. ing. Bloch, Berlin. Berlin: W. Junk, 1925. Pp. 522.

The work in hand is a cyclopedic compilation of biological tables, the work of seventy-three contributors. The completed work will consist of four Royal octavo volumes, of which this is the first. There will be an alphabetical index, over two thousand pages with plates, partly colored and numerous illustrations and the entire work will probably be completed during the course of this year.

This is undoubtedly a unique publication, the first of its kind, which is destined to fill a long felt want of investigators, teachers and practitioners. It will supply data that have to be sought in various textbooks on medicine, anatomy, physiology, hygiene, physics, chemistry, zoology, botany, technics, immunology, pharmacy and bacteriology, and frequently the data are not available in these sources. What is more, the data are reliable, having been furnished by authorities in their respective fields. The constants and data supplied include the whole field of biology and the borderline sciences. The information is available at a glance, thereby saving much time and effort. If further reference is required, the quotations of all the original works are also given. Explanations of the tables and methods of computation are fully and explicitly detailed.

The following are the subjects included in the first volume, with their respective contributors: Tables of logarithms, trigonometric and other important mathematical formulas, physical units, and the units of mensuration and weight used in all countries, by Block; the hardness, density, ductility, and elasticity of the most varied materials of vegetable and animal tissues, discussed in every possible aspect, by Kisser and Cronheim, respectively; the extent of motion of the individual joints, the origins and insertions of muscles (tabular form), the centre of gravity, and data on walking, flight, swimming and jumping (special physiology of muscle), by du Bois Reymond; general hydrodynamics and aerodynamics, by Schiller; physiology of the cir-

culation, by Lehmann; the dissemination of plant material (seeds) by the air, by Metzner; the physics of optics, by v. Rohr and Kessler; the mathematics of optics, by v. Rohr; solar and celestial irradiation, by Kessler; artificial sources of light, by Bloch; the transillumination of plant and animal tissues, by Metzner and Pincussen, respectively; the anatomy and physiology of the eye, by Steindorff; the spatial sense of the eye, by Hofmann; the objective effects of light upon the retina and facial sensations, by Kohlrausch and Feufer; acoustics, by Block; physiological acoustics, by Schaefer and von Hornbostel; heat: thermometry and gas volumes, by Bloch and Gyemant; specific heat, critical data and conductivity, by Gyemant; the conduction of heat, by Korff-Petersen; medical climatology, by Dorno; body temperature, by Kanitz; cryoscopic and osmotic values, turgidity, plasmolysis, permeability of dyestuffs and neutral salts, by Grafe; the steam pressures of various substances at different temperatures, by Gyemant; the physical chemistry of vegetable tissues, by Grafe; the physical chemistry of the blood and of tissue juices, by Loeb; and anesthesia, by Winterstein.

This is a standard work that should find a welcome in every medical institute, clinic and scientific laboratory.

THE EXPECTANT MOTHER

Approaching Motherhood. Questions and Answers of Maternity. By George L. Brodhead, M.D. New York: Paul B. Hoeber, 1925.

This practical and clearly written little manual is, as its subtitle indicates, a sort of quiz compend for the expectant mother, giving in a series of hypothetical questions and terse answers the essentials of anatomy and physiology, including the signs of pregnancy. There are chapters on various phases of maternity from conception to lactation, on confinement, convalescence, nursing and the care of the baby. The questions of diet, dress, exercise, in short of hygiene of the various stages, are answered briefly and with common sense. Not the least interesting chapters are those dealing with popular fallacies such as maternal impressions, exercise and diversion, and discomforts of pregnancy.

ARROWSMITH

Arrowsmith. By Sinclair Lewis. New York: Harcourt, Brace & Co., 1925. Pp. 448.

Martin Arrowsmith is never a character in a book. No matter how minded the reader, the man Sinclair Lewis has written down, lives. And we quarrel with or welcome this muscle-bone-and-sinew person, feel with him, approve or disapprove of his actions, with the sublime disregard of his fictional setting. As stern a test as any for craftsmanship, vitality of theme. Sinclair Lewis has written a real novel.

Arrowsmith may have been a genius. We do not think so. Rather he was an average young man whom the gods of family and convention had fortunately overlooked. The usual dower of potentialities is his and he develops freely because he always dares to be himself. Not in any selfconscious way. The best counterirritant for selfconsciousness is some such all absorbing interest as research. Arrowsmith never sets a material goal before him like his fellow students. His life is one continuous pursuit of a goal. Every one of the others achieves what he has set out for—success, mediocrity. Only Martin with his freedom from the "done thing" arrives at—what? The knowledge that life is a grim and pitiful science, fascinating, inexorable. That the only opiate is work, the only god self. And that unending war is, was and ever shall be waged between man and nature.

The satire of *Arrowsmith* is a boomerang. It begins with the reactions of readers. Just as the medical staircase climbs from the all sufficient country doctor to the highest salaried mouthers of bunk, so each stratum of readers sees through or is piqued by a ruthlessly uncovered familiar strain of humanity. There are not many Arrowsmiths among us, but there are countless Almus Pickerbaugh's, Irve Watters, Angus Duers for us to defend.

Then there are the women in Arrowsmith's life history. Apparently Sinclair Lewis feels that the thinking mind must inevitably be solitary. A comradeship between Martin and his wife is possible only because she lets herself become his shadow. Naturally it would have been far healthier for Leora to have had a life of her own. She merely follows the pathway of least resistance, sinks herself in Martin, is lost. And by the bitterest irony the child that might have saved Leora is born to Joyce, the second wife, to whom it means nothing in terms of reality—a plaything, a pride, or a nuisance.

From the drudgery of medical school to the drudgery of living, the relentless path of Everyman gathers in its wake all seekers, all thinkers. All along are stopping places. And those that halt for a breath stay. Beyond lies, not happiness, nor satisfaction, nor success—just beyond—the sun that never sets, the question that makes or breaks a man.

VAL SINESTRA

Val Sinestra. By Martha Morton. New York: E. P. Dutton Company, 1925. Pp. 275.

Rather a slow moving story of supposedly volcanic passions. Many factors are hurled into its making, why one cannot quite tell, since comparatively little is made of them once they are blended. Centuries of turbulent ancestors produce two characters, the woman, a Catholic Jewess, the man, son of Swiss emigrants whose hearts break in exile. The other man is the barrier, convention, the husband. There is the struggle of the wife who is afraid of the things she wants, of the man who has never before been frustrated, of the husband who fears and dreads his fortune in marriage. There is a nurse thrown in, the perfect companion for the tortured husband. Noble resignation on all sides. The result, a culture medium bristling with the bacteria of morbidity, neuroses, masochism. From this mess springs a son. We think the author wants him to be the child of the lover but doesn't quite dare put it across. The lady is tormented as much by the fact that she did not bear her lover's child as she is by her continued guilty love. Everyone wallows in purple emotions.

And then there are sets of conservative Old New York, ancestral mansions full of antique treasure, modern palatial Park Avenue, Nature at home in the Swiss mountains, the cataclysmic rendezvous of the lovers at Val Sinestra in the storm, the accident, the miracle. Watch for the film at your local theatre!

Medicoliterary Notes.

Two recent books that have been put into Braille for the blind are E. Torday's *On the Trail of the Bushong* (Lippincott), and Prof. J. Arthur Thomson's *Outline of Science* (Putnam).

The Library Service Bureau of the Franklin Square Subscription Agency names as follows the ten outstanding magazine articles in July publications: The Limitation of Armaments, by Rear Admiral Bradley A. Fiske in *Harper's Magazine;* Heredity—the Master Riddle of Science, by E. M. East in *Scribner's Magazine;* And So I Threw Away $20,000 a Year, by Edgar Lee Masters in the *Cosmopolitan;* The Moral Value of War, by George Wheeler Hinman, Jr., in the *Forum;* When I Was an Editor, by Jerome K. Jerome in *Harper's Magazine;* America Learns How to Play, by Weaver Pangburn in *McClure's Magazine;* Transplanted Men, by Edward S. Martin in *Harper's Magazine;* Whitewashing Jane Clemens, by Doris and Samuel Webster in the *Bookman;* Making a Wreck of the Veteran, by William Edler in the *American Mercury;* and Your Business and Mine, by George E. Roberts in the *Review of Reviews.*

* * *

The U. S. Veterans Bureau has recently issued a report on Hospitalization of War Veterans Today, by Inez M. Pugh. The bureau is now operating forty-nine hospitals, seventy-four dispensaries, ninety-four clinical laboratories, and about one hundred x ray laboratories, and is housing twenty-nine thousand patients.

* * *

Recent publications of McBride's, all suitable for summer reading, are a study of Edith Wharton by Robert Morss Lovett, one of the series of *Modern American Writers,* edited by Ernest Boyd; *Regarding the French,* by Moma Clarke, attractively illustrated with black and white drawings by A. Pecoud; *The Keys of the City,* by Elmer Davis, a jolly adventure story; and *The Letters of Rosa Luxemburg to Karl and Luise Kautsky.*

* * *

Harry Kemp, some of whose works have so furiously excited the censors, is reported to be on his way to Spain in search of material for a group of Spanish plays that he plans to produce next fall in the Poet's Theatre in New York.

* * *

A recent noteworthy publication from the Yale University Press is entitled *Social Aspects of Mental Hygiene;* Addresses by Frankwood E. Williams, C. Macfie Campbell, Abraham Myerson, Arnold Gesell, Walter E. Fernald, and Jessie Taft; with a foreword by James Rowland Angell and an introduction by Maurice R. Davie.

* * *

Brentano's announces for fall publication a volume of short stories of Oriental life by Achmed Abdullah. Three of Mr. Abdullah's plays will be produced next season in New York theatres, namely, *The Passionate Prince,* with Lowel Sherman as star; *Black Tents,* starring George Gaul; and *The Savage,* to be produced by Belasco.

* * *

Apropos of the legislation recently formulated by the British Government which will impose severe sentences on the practitioners of "witchcraft" in Kenya, and also on the headmen of the tribes who condone the offence, the *Manchester Guardian Weekly* tells us that superstition is by no means dead even in Great Britain, and to prove its point, refers to the trial last winter of a Devonshire farmer who was sent to jail for attacking a woman who, he believed, had bewitched his pig.

What will be the highest funicular railway in the world is now being constructed on Mont Blanc. It will run from Chamonix to the summit of the mountain. The system used is that of overhead cars suspended from a steel cable. The cars carry eighteen passengers apiece and travel at a speed of about six miles an hour.

* * *

In a recent issue of *Néoplasmes,* an international medical journal devoted to cancer research, Drs. Kotzareff and Weyl of Geneva describe their method of injecting directly into the blood a serum containing radium emanation. This serum is preferably made from the patient's own blood, and can be prepared in less than two hours and applied the same day. Its originators claim as its chief merits that it overcomes the difficulties of the application of radium rays or of multiple practice; and that the whole radioactive force of the emanation is brought into play with an astonishing uniformity and without the destruction of healthy cells.

Many of us will be surprised to learn that New York city's homicide rate for 1924 was well below the average of other large cities in the United States, and this in spite of the fact that our murders numbered 387, an increase of 79 over the number in 1923. Frederick L. Hoffmann, consulting statistician for the Prudential Insurance Company of America, in an article in a late issue of the *Spectator,* states that New York stands thirty-fourth in the study of the seventy-seven other municipalities on which the figures are based, and has a rate of 6.4 per 100,000 population. The average for the seventy-seven cities was 9.9, almost double the rate of twenty-five years ago, a fact that causes the writer to state that "the murder situation in America is worse than ever." He estimates that the annual toll of murders now exceeds 11,000. The greatest number of homicides was in Chicago, which had 509 and a rate of 17.5, New York was second, and Detroit third with 211.

* * *

An enterprising Boston journalist has unearthed the fact that the wreck of the Hesperus never took place in fact but only in the mind of the poet, Longfellow. The maritime records for 1839 tell of a great storm on December 15th, when, among twenty other vessels, the Hesperus was driven into Boston Harbor. The only damage this ship sustained was a broken bowsprit. Longfellow's diary for December 17th reads: "News of shipwrecks. Horrible. Off the coast, Twenty bodies washed ashore off Gloucester, one female being lashed to a piece of the wreck. . . . I must write a ballad upon this."

* * *

Incidental to Pirandello's visit to London and the production of some of his plays at the new Oxford Theatre, the manager has obtained the censor's approval of all except *Six Characters in Search of an Author,* which had a lengthy and successful run in New York two seasons ago. The ban makes those of us who saw the play here ponder on what the censor's objection of "immorality" can be.

* * *

Reading matter for summer a little more serious than fiction is suggested as follows: *The Crisis in Psychology,* by Hans Driesch (Princeton), a discussion of some of the problems of modern psychological research; *The Crowd,* by Gustave Le Bon, a new edition of a popular book (Fisher Unwin); *The Life After Death in Oceania,* by Rosalind Moss, a review of the burial customs and beliefs of the peoples of Polynesia, Melanesia, and Indonesia (Oxford); *Approaching Motherhood,* by Dr. George L. Brodhead (Hoeber); *The Science of Biology,* by George G. Scott (Crowell); *Newman as a Man of Letters,* by Joseph J. Reilly; *Playwrights of the New American Theatre,* by T. H. Dickinson, a discussion of "the roots of the American drama," with special chapters on Percy Mackaye and Eugene O'Neill; *Hull Down,* by Sir Bertram Hayes, an account of the happenings of forty-four years at sea, the last three titles published by Macmillan; and *Adventures of a Scholar Tramp,* by Glen H. Mullin; *The Wisdom of the Hebrews,* by Brian Brown; *The Personal Equation,* by Dr. Louis Berman; *What I Believe,* by Bertrand Russell, and *Credo,* by Edward Stewart White.

* * *

In a recent report of the Bureau of Mines it is stated that the annual loss through smoke for each person in the larger industrial cities in the United States is approximately $7.06. The yearly smoke bill for Philadelphia, for instance, is $16,852,000. This loss could be obviated by the use of modern stoking equipment.

Parts of the Tower of London that have never in all its history been opened to the public have recently been restored, in so far as that is possible due to vandalism committed in order to fit certain rooms for tenantry by the keepers, and may now be seen as they were originally when the old inscriptions were cut deep into the stone of their walls and floors by the tortured souls confined there who found this their only means of employment and recreation.

Abstracts from Current Literature

PEDIATRICS

Congenital Infantile Hypertrophic Stenosis of the Pylorus.—Emory G. Alexander (*Medical Clinics of North America,* November, 1924) states that the more modern view of the etiology of congenital infantile hypertrophic stenosis of the pylorus ignores the possibility of primary pathological overdevelopment of the muscle, but seems to incline toward regarding the hypertrophy as the result of faulty embryonic development which leads to an actual stenosis of the pyloric orifice, a condition which occasionally is demonstrable at operation, the hypertrophy of the muscle in turn being due to the increased effort required to force the food from the stomach into the duodenum. In other words, a compensatory hypertrophy. The development of the hypertrophy being slower in some children than in others accounts for the variation in age at which the obstructive symptoms appear. The disease shows more frequent involvement and more serious affection in boys than in girls. The symptoms may develop at any time from the seventh or eighth day to the sixth or eighth week of life or beyond that. The fact that most of the babies are breast fed infants excludes faulty diet as a possible cause of the condition. Diagnosis in most cases is not difficult, the most characteristic symptom being the persistent projectile vomiting.

The chief objective symptoms are vomiting and constipation. The onset is sudden. At first vomiting may be irregular without any definite relation to feedings, but soon it occurs from fifteen to thirty minutes after each feeding, which is given up entirely unchanged. As the disease progresses, the vomiting becomes less frequent but more copious, that is, it is cumulative as well as projectile. There is evidence of retention. In addition to milk, the vomitus contains swallowed saliva. Blood or bile in the vomitus is rare. The stools may take on the character of meconium. The child is constantly hungry, the bowels are constipated, and emaciation and loss of weight are rapid.

The abdomen is tense with a marked rounded prominence at the epigastrium, and there is resistance to palpation, sometimes also rigidity. Peristaltic waves across the abdomen, when present, are more or less pronounced, but not painful. The waves usually begin below the left costal margin, extending toward the median line and to the right hypochondrium beyond the region of the pylorus. When present, the tumor can be described as a round or cylindrical mass which rolls under the fingers, generally located from one to two centimetres to the right and above the umbilicus. The absence of a tumor need not exclude the diagnosis of congenital hypertrophic pyloric stenosis. Patency of the pylorus is usually determined fluoroscopically. Retention at the end of four hours of twenty-five per cent. of the barium meal clinches the diagnosis and may be taken to indicate the necessity of surgical interference. This condition should be differentiated from a spastic condition of the tract, which usually gets well without operation.

The consensus of opinion today is toward surgical treatment, although there are a few authorities who think that it can be relieved medically. The pylorospasm can be controlled by atropin, usually 1/1000 grain with each feeding, given until the desired physiological effect is obtained. This may take from two weeks to almost a year. No doubt there are cases of mild pyloric stenosis which will recover under medical treatment, but the severe cases will almost surely "die in the process" unless operated upon. Not infrequently under this plan of treatment the cases are brought to the surgeon in a state of dehydration and acidosis, altogether in a desperate condition. Preliminary treatment is often necessary. This consists of soda and glucose per bowel and intraperitoneal salt solution. General anesthesia is preferable to local anesthesia. The Rammstedt operation is the most popular at this time.

Convalescence is generally uncomplicated, provided proper postoperative care is given. This consists in maintaining the body heat with hot water bottles, and the administration of stimulants when indicated. If the postoperative vomiting is severe it can usually be relieved by gastric lavage. Feedings can be resumed almost as soon as the infant comes out of the anesthetic. Breast milk diluted is the most desirable. As a rule a low fat formula, one or two teaspoonfuls every two hours, with a small quantity of water between feedings is well tolerated. Protein milk or condensed milk is also useful. The amount is gradually increased until two or three ounces of milk are given every three hours interspersed with water. Extra amounts of fluid can be supplied by intraperitoneal saline given slowly or proctoclysis or hypodermoclysis of normal saline or soda bicarbonate and glucose for the first few days. Most of the patients are discharged within twelve to twenty days after operation.

Protein Milk as an Infant Food.—Sidney V. Haas and Louis H. Barenberg (*Archives of Pediatrics,* November, 1924), assert that eiweiss milk, prepared according to the method described, is satisfactory for prolonged use. The ingredients required are: 1, commercial buttermilk (bottled), which is prepared from fat free milk; 2, twenty per cent. cream, which is prepared by taking the top four ounces from a quart bottle of whole milk; 3, dextrimaltose. To one quart of buttermilk add one quart of water, bringing to a temperature of 135° F., remove from the stove and let stand half an hour, then remove one and one eighths quarts of whey, mash remaining whey and curds through a fine hair sieve, and add four ounces of twenty per cent. cream and sterile water, if necessary, to make a total of one quart. Percentage of sugar desired. The final product is a homogeneous mixture, consisting of very fine, soft curds, which remain in suspension for a considerable time, and pass readily through a fairsized nipple opening. It must not be overheated before feeding, else the curds separate. The taste is more agreeable than when prepared by other methods; odor and taste are slightly sour. This preparation will keep forty-eight hours.

This mixture is a suitable food for infants up to two years of age. It is particularly indicated in gastrointestinal disorders and marasmus and for premature babies, and celiac and infectious diseases. It is palatable and ordinarily well taken after a day or two. It is given undiluted, even to premature infants. The gain in weight is equal to that obtained by any other form of milk, and it is not temporary but progressive. The average gain in weight for all ages over the entire period was found by the author to be four ounces a week. The minimum average, 2.25 ounces; the maximum, 6.5 ounces. It seems to exert a protective action against ketosis, intoxication and gastroenterities in infants. Infants do not develop excoriation of the buttocks. Tolerance for this preparation is only equaled by that for breast milk.

Technic of Puncture of the Lateral Ventricle in Infants.—D. Miskolczy and K. Waltner (*Monatsschrift für Kinderheilkunde,* November, 1924) propose the following technic for puncture of the lateral ventricle in infancy:

An ordinary long, thin Record needle is used. The proper point of puncture, the direction of the puncture and its depth must be determined. The proper direction of the puncture is governed by three planes: 1, the sagittal plane crosses the internal angle of the eye; 2, the frontal plane runs through the middle of the space between the external angle of the eye and the uppermost point of insertion of the auricle; 3, the horizontal plane passes through the upper bony border of the superciliary ridge. The point of insertion of the needle is the point where the sagittal and frontal planes meet on the scalp and the direction of the puncture is the line where these two planes meet. The depth of the puncture is determined by the distance from the top of the scalp to the level of the eyebrows lying in the hoizontal plane. This depth should be marked on the needle before it is inserted. The point of puncture thus determined lies in the region of the fontanelle only up to a certain age, or up to a certain size of the fontanelle. When this is no longer the case, one must approach the frontal plane in a median direction until the fontanelle is reached. When this point is at least three to five mm. distant from the midline, one need not worry about injuring the longitudinal sinus. When this point lies nearer than three to five mm. to the midline, one approaches toward the anterior edge of the fontanelle in a posterior direction, until the desired distance is reached. The puncture must then be made somewhat externally and anteriorly, followng the directions mentioned

above. The point of puncture should always be made anterior to the coronary suture and never behind it.

The child should lie flat on its back and at such a level that the fontanelle of the infant and its face should be on the same level with the head of the physician. When the desired level of puncture is reached the syringe is attached to the needle and gentle sucton is made. The aspiration of clear cerebrospinal fluid shows that the lateral ventricle is punctured. If no fluid appears, the puncture is not successful. Blind stabbing must be avoided and the needle is preferably withdrawn.

New Methods for Making Esophageal Strictures Visible and Photographing Them, Particularly in the Case of Children.—Arthur Pollerman (*American Journal of Diseases of Children,* November, 1924) proposes the use of two methods to overcome the difficulties encountered with other methods.

1. Rubber tubes of different sizes, impregnated with lead, are sealed at one end and may be easily inflated. One of these tubes is drawn over a well oiled bougie and inserted into the esophagus, after which the bougie is withdrawn and the tube inflated. The walls of the inflated tube conform closely to the walls of the esophagus and permit the observation of the esophageal walls and of any stricture or other deformities. In the case of young children it is more convenient to inflate the tube without withdrawing the bougie. This method is easy and convenient and of advantage in most cases, excepting where there is a very narrow stricture or a very great diverticulum.

2. In cases where the tube cannot be used, the alternative technic is the administration of a suspension of bismuth subcarbonate in an emulsion composed of: oil of bitter almond, eight parts; gum arabic, four parts, and water, eight parts. This emulsion yields an easily perceptible and very even shadow, which is not displaced so quickly by the peristalsis of the esophagus. It shows the walls of the diverticulum of the esophagus as well as the narrow lumen of the stricture. As little as one or two teaspoonfuls are sufficient in most cases.

Diagnosis of Dilatation of the Bronchi in Children by Means of the Injection of Iodinized Oil.—P. Armand-Delille and C. F. Gelston (*American Journal of Diseases of Children,* November, 1924) recommend the following procedure for the diagnosis of dilatation of the bronchi in children. It is useful to disprove or prove the presence of bronchiectasis. It is not prudent systematically to practise this injection in tuberculous patients, because of a tendency toward congestion. It is also useful in cachectic patients with nummular sputum, suggestive of tuberculosis, and in cases primarily diagnosed as interlobar pleurisy or pulmonary abscess; also in the possible presence of an hepatic, subdiaphragmatic, or perirenal abscess.

A specially designed trocar is used, which is inserted through the cricothyroid membrane. It is made on the principle of the tracheotomy cannula, but smaller. A vegetable oil containing 0.54 gm. of iodine to the cubic centimeter is used. The oil must be warmed. The child is given 0.005 gm. of morphine sulphate a half hour before instrumentation. The patient is placed horizontally on the fluoroscopy table in the usual position for tracheotomy. After applying local anesthesia over the cricothyroid membrane, the trocar is forced through the tissues perpendicularly to the larynx. When the stylet is withdrawn, a whistling sound denotes a correct position. The syringe containing five c.c. of procaine is now attached, the head of the patient is slightly withdrawn from its extreme hyperextension, and slight pressure is exerted. A forcing out of the piston and the presence of air bubbles caused by the slight cough incident to the irritation of the first few drops of the solution confirm the correct position of the trocar in the trachea. The iodinized oil is then injected not too rapidly. From eight to ten c.c. of oil suffices as a rule to inject the bronchial tree of one lung, in children aged from seven to fourteen years, and requires from six to eight minutes.

The child is then immediately radiographed in a horizontal position. Fluoroscopy will demonstrate if there has been sufficient oil injected, in which case the trocar is withdrawn. There is no hemorrhage and no dressing is needed. Radiographs are then made in the vertical position.

The contrast between other radiographic reproductions and those obtained with iodinized oil offers extremely valuable information and should permit of the following conclusions.

With a picture of multiple shadows in the neighborhood of the hilum with an excessive bronchial ramification, the shadows being joined to the bronchi by a pedicle, the diagnosis of bronchial dilatation is justified. If the shadows are confluent but can, nevertheless, be separated by careful examination, the diagnosis of dilatation of the bronchi is again established. If the larger bronchial ramifications, without showing bunched localized shadows, appear noticeably enlarged one must admit a cylindric dilatation of the bronchi. Finally, if there is simply a question of shadows along the smaller bronchial ramifications, when they are compared to the normal picture, one may establish the presence of a moderate degree of bronchiectasis. Tuberculous cavities, which are easily enough diagnosed by ordinary röntgenograms, may be disregarded. Such cavities are usually located far from the hilum and the mediastinum, above the diaphragm, and are usually single.

Emphasis should be placed on the fact, however, that this procedure is not entirely innocuous, but it furnishes valuable and important information regarding the normal and pathologic appearance of the bronchial tree in children. The local application of iodine may even have a therapeutic value, as a recession of symptoms and a diminution of physical signs has been observed.

Hypoglycemia and Acidosis in Fasting Children with Idiopathic Epilepsy.—Edward B. Shaw and Margaret Moriarty (*American Journal of Diseases of Children,* November, 1924) found that in a series of five epileptic children, ten to fourteen day fasts were accompanied by: 1. An increase in blood uric acid. 2. Moderately marked acidosis, as indicated by acetone excretion in the breath; diminished alkali reserve; moderate fall in pH of the plasma. 3. A striking decrease in the blood sugar. 4. A slight diminution in degree of acidosis and rise in the blood sugar during latter days of fast. It is suggested that the diminution of blood sugar indicates the greater case of depletion of carbohydrate stores in childhood, and helps to explain the increased tendency to acidosis.

Nonrachitic Softening of the Ribs in Infants and Children.—Alfred F. Hess (*American Journal of Diseases of Children,* November, 1924) states that softness of the ribs and of the anterior thoracic wall is not necessarily a sign of rickets, although it may be brought about or intensified by this disorder. It is associated preeminently with the atrophic in contradistinction to the well nourished infant, two groups which should be differentiated in considering rickets. Infants who have never had rickets may nevertheless show softening of the ribs. It is found frequently in the newborn, especially those born prematurely, and may persist for years. In these cases there can be no question of a rachitic origin. Finally, it is not alleviated or cured by prolonged treatment with the two specifics for rickets, cod liver oil or ultraviolet irradiation.

Cervical Ribs in Children.—A. H. Southam and W. J. S. Bythell (*British Medical Journal,* November 8, 1924) draw the following conclusions: 1. Cervical ribs are congenital abnormalities and may be found in children at all ages. 2. In thirteen recorded cases twelve were bilateral and ten occurred in girls. 3. Their diagnosis will frequently only be made after röntgenographic examination. 4. In the majority of cases symptoms do not appear till adult life is reached. 5. The delay in the onset of symptoms may be due to the ossification of the rib, which is not complete till about the twenty-fifth year. In young children, however, they occasionally give rise to definite symptoms in the upper limb similar to those seen in adults. 7. In others their presence may lead to a diagnosis of spinal caries or torticollis, and the differential diagnosis can be established only by röntgenography. 8. Only rarely will treatment by operation be considered necessary.

Peritonitis in Scarlet Fever.—An analysis of the cases of E. S. Platou (*Archives of Pediatrics,* August, 1924) indicates that they fall into one of two groups: 1, those occurring early in the disease, concomitantly with a profound sepsis; 2, those which occur late and which are sometimes secondary to another complicating focus of infection. Of these, the early type seems to have a greater tendency to be generalized, and is believed by some to be a peritoneal manifestation of the eruption. The wisest therapeutic procedure is to defer operation as long as the condition of the patient will permit; then to perform a laparotomy, rather than to hope for adequate drainage through the rectum.

Studies in Scarlet Fever. — Konrad E. Birkhaug (*Bulletin of the Johns Hopkins Hospital,* February, 1925), undertook the study reported to determine the comparative value of convalescent scarlet fever serum and Dochez's scarlatinal antistreptococcic serum in the treatment of severe cases of scarlet fever. Thirty-seven patients with severe scarlet fever were treated during the first seven days of their disease with convalescent serum, the average dose being twenty c.c., given intramuscularly. Satisfactory recovery without complications occurred in thirteen of the thirty-seven cases; twenty-two patients showed temporary improvement, although complications developed and prolonged their convalescence, but eventually they recovered and were discharged in good condition. Two patients, moribund on admission, died from streptococcus beta hemolyticus septicemia. Thirty cases of scarlet fever were treated in the first four days of the disease with Dochez's serum, and one case on the seventh day. In seventeen cases the rash extinction phenomenon was demonstrated prior to the administration of the therapeutic dose of therapeutic serum, and in every instance this test was positive. The average dose of serum injected intramuscularly was forty c.c. Of the thirty-one patients treated, twenty-five recovered in from two to four days, without the development of complications. Three showed definite improvement after two to four days, and although minor complications occurred during convalescence, they were discharged completely recovered. Three patients, admitted in a moribund condition, died from streptococcus hemolyticus septicemia and pneumonia. The cases presenting septic complications yielded slowly and irregularly to Dochez's serum.

Postoperative Acidosis in Children.—Philip C. Jeans and Kenneth H. Tallerman (*British Journal of Children's Diseases,* October-December, 1924) studied the question of the causation of postoperative acidosis in children. The blood and urine before and after operation were followed, and those substances which might be causative factors were estimated. They found the lowering of the alkali reserve to be due in but small measure to acetone bodies, or to lactic acid accumulation. Phosphate retention is obviously not the cause of any acidosis that may exist. In fact, phosphate excretion constitutes a compensatory mechanism, the phosphates of the blood failing with a lowered alkali reserve, and the phosphate excretion being increased coincidently. The organic acids excreted increased, and in those instances showing a more marked lowering of the blood carbon dioxide, were in excess of both acetone bodies and lactic acid. It is therefore presumed that some as yet unidentified factor is largely responsible for that lowered alkali reserve which is observed. The fall of the carbon dioxide appeared proportional to the drop in blood pressure. It was observed also that qualitative tests for acetone bodies in the urine gave but a poor indication of the degree of acidosis present, if compared to the variation in alkali reserve.

Anteroposterior Tilt of the Pelvis: Its Variations, and Their Clinical Significance in Children.—Edgar F. Cyriax (*British Journal of Children's Diseases,* October-December, 1924) states that the causes that may induce pathological variations in the anteroposterior tilt of the pelvis are numerous. Posture and the assumption of vicious attitudes play an important part, just as these factors do in the production of lordosis and kyphosis elsewhere, and the effect of reflex contractions as the result of abdominal and pelvic disorders must not be overlooked. Among other causes not usually appreciated may be quoted the following: 1, Wearing of high heels; 2, partial spondylolisthesis; 3, weakness of the anterior abdominal muscles; 4, increase of power in the flexors of the pelvis; and 5, walking with the toes turned out too much.

The results of pathological alterations in the anteroposterior pelvic tilt fall under two heads: 1, the production of abnormal curves in the vertebrae above; and 2, the production of pelvic trouble. This may be brought about through several channels: alterations in the state of tonus or increased degree of contraction of the psoas muscles; alterations of excitability in the sympathetic nerves that lie on the psoas muscles of the latter are hyperemic or congested; impediment of some of the venous return and the lymph flow from the pelvis.

The treatment of pathological anteroposterior tilt is first to remove any causes, primary or secondary, that may be present, and subsequently or coincidently, to strengthen the muscles that will tend gradually to pull the pelvis back into its original position—remedial exercises. The importance of the recognition and correction of abnormal pelvic tilts is obvious, for the presence of this tilt means alteration of position and angle, both relative and absolute, of some or all of the abdominal and pelvic organs. It must be borne in mind that the function of any organ may vary directly in proportion to alterations of its correct position. It will be found that merely correcting the architectural defects may cure the conditions just mentioned. The examination of the degree of the anteroposterior pelvic tilt should form an integral part of the routine examination of spinal curvatures in general.

Effect of a Small Breakfast on the Energy Metabolism of Children.—Virginia Bauer and Katherine Blunt (*Journal of Biological Chemistry,* February, 1924) repeatedly observed seven children early in the morning and again on the same day about four hours after a small breakfast, in order to determine whether basal metabolism determinations could be safely made on children at noon instead of before breakfast. The average oxygen consumption at the later hour was only 0.6 per cent. higher than before the meal. The use of the noon hour is, therefore, to be considered safe as a routine procedure provided the breakfast does not exceed 470 calories with not more than 14 gm. of protein and is eaten at least four hours before the metabolism observation.

Mother's Milk as a Source of Infection in Epidemic Pemphigus Neonatorum.—Ralph R. Mellon, Dorothy Caldwell and W. W. Winans (*American Journal of the Medical Sciences,* March, 1925) maintain that the evidence submitted is at least presumptive that certain outbreaks of pemphigus neonatorum are traceable to an initial case infected by its own mother's milk. Such findings occurred three times in sporadic cases that might have given rise to outbreaks had not the mothers been segregated, while in a third sporadic case with these findings an outbreak of ten cases actually did result. A similar outbreak was also traceable to a burn infected with aureus, suggesting a diverse origin for the infecting cocci. No epidemiological type could be associated with the disease, the organism being serologically the same as those isolated from abscesses, etc. When the Staphylococcus aureus is rampant, as it has been for several years, it may be present in the milk and even in the blood stream of certain mothers with few or no symptoms, who may be viewed as carriers. The mild infection in one mother resembled in no way true impetigo, which fact fails to support the theory that pemphigus neonatorum and impetigo contagiosa bullosa are identical diseases. By concentration of attention on this means of transfer we do not intend to minimize the predominant role played by case to case contact, undoubtedly the common method of transmission in institutions, but from a public health viewpoint it would seem highly important to isolate both mother and child when it can be shown that the mother harbors the infecting organism.

The Potentially Undernourished Child.—Arthur M. Kimberly (*Boston Medical and Surgical Journal,* March 26, 1925) makes the following valuable suggestions: "Recognizing in the perfectly healthy infant of one year the potentially undernourished child of this later period, it devolves upon us to urge the importance of continued supervision and weight recording during this period. We must teach that errors in diet and hygiene at this time may breed serious consequences, often the more so, because their onset is insidious. We must insist that children require, if anything, greater regularity of schedule with even more rigid preservation of sleep and rest periods than formerly. We must emphasize that the child is still essentially a baby and requires the same careful selection of food as he did when he was an infant.

In regard to food habits: we must discourage the promiscuous sampling of food at the table; and we must insist that children be taught to eat unquestioningly the food that is set before them, urging, if necessary, a prompt withholding of other foods until properly trained. His management must be guided by the principle that the adults must set the example of correct food habits, and must be inspired by the assurance that a child *can* be taught to eat and enjoy the foods that are good for him. We must urge that his training may be accomplished more readily by the force of approbation, enthusiasm and encouragement than by dogmatic commands. On the other hand we should teach that if merited his punishment should follow with inevitable certainty and,

as far as possible, have an educative value. We should be prepared to provide suitable diets containing adequate mineral matter, roughage, vitamins, and total calories properly balanced. The mother should be warned how easily children become overfatigued and consequently irritable. Respiratory infections must be guarded against; immunization carried out at proper times; and convalescence should be prolonged until normal weight and strength have been regained. Social adjustments should be made, so far as possible, to prevent friction and abnormal mental strain. Success in carrying out such a preventive program for the pre-school period will require a well formulated office outline with a definite program of the health habits that shrould be acquired at each age period. Painstaking inquiries into the child's habits and activities must be made and a shrewd insight into the home situation must be obtained.

Obesity in Children.—F. S. Langmead and Edwin G. B. Calvert (*Lancet,* November 29, 1924), in a discussion of this subject, with special reference to carbohydrate metabolism and its modification by the administration of certain ductless glands, draw the following tentative conclusions, as their investigations are still incomplete: 1. The blood sugar curves in cases of great obesity in children—too readily called hypopituitarism—are diverse in their outlines. 2. In two such cases the administration of posterior pituitary substance led to a normal curve, favoring the view that in cases of hypopituitarism it is the posterior lobe which is chiefly concerned with the altered carbohydrate metabolism. Its extract pituitrin, however, had less influence. 3. In a third case, with more normal general development and with normal sexual development, the anterior lobe had the correcting effect. 4. The slightly inferior influence on the blood sugar curve of the whole gland substance in the above three cases appears to indicate that in these cases the good effect on carbohydrate metabolism obtainable by giving the appropriate gland substance may be counteracted to some extent by combining it with the extract of the other lobe. 5. Incidentally, these experiments appear to show that pituitary gland substance given by the mouth is not inert. As far as carbohydrate metabolism goes, the blood sugar curve being used as an index, it seems logical to administer that lobe of the pituitary which produces the better effect on sugar tolerance. However, considering the cases generally, it will be noticed that the whole gland gives quite good results. In one case the addition of a small dose of thyroid improved matters. On the whole, the results might be construed as indicating that a properly balanced pluriglandular therapy is required for such cases as these; the suggestion has a pharmacological rather than a physiological basis. 6. Thyroid extract may reduce weight in cases of this kind, but it can hardly be considered as an ideal remedy per se, in that it does not restore carbohydrate metabolism to normal. 7. Possibly the reduction of a normal blood sugar curve may prove a useful guide to treatment, since when this happened with pituitary substance the patient's condition improved generally. 8. Possibly, too, a somewhat restricted diet, in which the protein is relatively increased, the carbohydrate curtailed, and the fat practically eliminated, may constitute one of the most effective means of stimulating metabolism and reducing weight. 9. The method of preparation from the testes of animals of what may possibly be their internal secretion is described, and also the very considerable loss in weight associated with its administration in one case reported.

RESPIRATORY DISORDERS

Extrapleural Thoracoplasty in Pulmonary Tuberculosis.—C. F. Gondolfo (*Bulletins et mémoires de la société médicale des hôpitaux de Paris,* July 17, 1924) asserts that no practitioner who institutes artificial pneumothorax in tuberculosis can now afford to neglect extrapleural thoracoplasty. The indication for it is absolute in a case of three or four years' standing with several acute recrudescences and a history of pleurisy during childhood or at puberty, or of cortical pleuritis for three or four months, followed by a change of the disease to a sluggish course, with evidences of fibrous disease on examination of the patient. Chest asymmetry is manifested in a marked retraction on the affected side; the supra and infraclavicular fossæ are depressed; the lowest intercostal spaces show evidence of inversion of the diaphragm; chest elasticity is reduced or lost, percussion eliciting zones with varying degrees of pulmonary or pleuropulmonary condensation; auscultation reveals small, but numerous disease foci, and fluoroscopy shows, aside from the tuberculous lesion, retraction of the mediastinum toward the affected side. In such cases an attempt at pneumothorax usually gives negative results, and general and climatic treatment have, as a rule, been tried and failed. The operation is necessary and permits the lung to retract to one fourth its original size. A second absolute indication is where pneumothorax fails to compress the diseased tissues on account of pleural adhesions. In these cases a partial thoracoplasty is done to complete the effect of the penmothorax. The third absolute indication is perforation of a cavity following a coughing spell, with infection of the pleura, or the pleural discharge of a pneumothorax which turns into a purulent discharge. In the first of these very ominous complications extrapleural thoracoplasty is the only measure affording permanent adhesions of the two pleural layers. The secret of successful thoracoplasty is its performance in three stages. This is because: 1, The technic is simplified and available to any trained surgeon; 2, shock is trifling and the pain during cough less; 3, the process of retraction takes place gradually and more naturally; 4, at the time of the second operation reconstruction of the chest wall has already begun and the ultimate deformity is less.

Extrapleural Thoracoplasty in Bronchiectasis.—C. A. Hedblom (*Surgery, Gynecology and Obstetrics,* June, 1924) presents a series of roentgenograms which he discusses with the following comment. While massive collapse of the lung has been achieved with marked relief of symptoms in all of these cases, it must be recognized that the diseased bronchi and lung tissue remain as a possible source of further acute exacerbation of infection. The persistence of cough and sputum may be due to an unrecognized involvement on the other side, but in some cases reported there are physical and röntgenological signs of persistent cavitation in the collapsed lung. If the symptoms persist, extirpation of the diseased tissue is contemplated.

Tuberculosis of the Larynx.—R. S. Pentecost (*Canadian Medical Association Journal,* August, 1924) urges a closer cooperation between the physician and laryngologist and says that early recognition of tuberculous involvement of the larynx is most desirable and regular laryngological examinations should be made of all patients suffering from pulmonary tuberculosis. The policy of *laissez faire* should be replaced by active local treatment. A large percentage of cases of laryngeal tuberculosis may be completely arrested by the employment of the following measures: Hygienic and dietetic treatment; absolute vocal rest; appropriate treatment of any associated pathological condition in the upper respiratory tract; heliotherapy; application of the galvanocautery to the affected areas in the larynx.

Criteria for Artificial Pneumothorax.—R. C. Wingfield and G. Selby Wilson (*Lancet,* July 26, 1924) say that if a relapse occurs during the exercise treatment in an artificial pneumothorax case, there are two salient points of interest: first, the longer it is, the worse is the prognosis; second, the earlier it occurs the less likely is the patient to do well. A relapse which takes place for the first time when the patient has reached an advance grade of exercise seems to be of singularly little importance. If a patient is going to do badly, he will relapse early; if he is going to do well, he will relapse late or not at all. A regular temperature is of good prognostic significance; an irregular one is the reverse. In men a periodical temperature is an unfavorable feature. The daily variation seems to have no special significance. Patients who have done well have more often had a complete collapse than those who have done badly. A considerable number of patients with bilateral disease are capable of responding well to artificial pneumothorax treatment, and of reacting favorably to the system of graduate exercise. The development of pleural fluid—so long as it be not of a purulent type—is a matter of supreme indifference to the prognosis. It appears that the advent of fluid is likely to be occasioned by exercise. Persistence of tubercle bacilli in the sputum after the induction of artificial pneumothorax is a bad prognostic omen. One of the most valuable criteria of the patient's reaction to treatment is the change in weight which occurs after his admission to the sanitarium. An early loss in weight should prove a most valuable arresting signal, and should lead to a careful reconsideration of the further treatment of the patient. The longer the patient's stay in the sanitarium the more

weight is he likely to gain or the less is he likely to lose. The author was mostly concerned with an examination of the results obtained by the graduated exercise treatment of patients on whom an artificial pneumothorax has been induced either by choice or by necessity.

Empyema.—Ambrose L. Lockwood (*Canadian Medical Association Journal,* October, 1924) presents the following points.

1. The incidence of acute empyema is about three times as common in males as females and except in traumatic cases, is as yet beyond the control of the medical attendant.

2. Apart from postural rest, inclining the patient on the affected side, or limited strapping of the involved side, the chest should not be tampered with in the developing stage of the disease.

3. Aspiration for diagnosis is rarely necessary.

4. Guided by the elevation of temperature, pulse and respiratory rate, the degree of dyspnea, the displacement of the heart, and the toxic condition of the patient, generally, aspiration should be delayed until the fluid is well walled off, and the lung about it firmly adherent to the chest wall.

5. If aspiration is employed therapeutically it should be resorted to at least every thirty-six hours depending upon the febrile reaction of the patient.

6. Intercostal incision or rib resection for drainage should only be employed after repeated aspirations of some form of closed drainage has failed to cure the disease.

7. Chronic empyema must be looked upon as the disastrous sequelae of a mismanaged acute empyema.

8. Radical interference with a chronic empyema cavity should only be undertaken after palliative measures have failed to obliterate the cavity.

9. Our aim should be to bring the collapsed lung out to the chest wall rather than to collapse the chest wall to the lung.

10. Above all we should constantly keep in mind that a combined mortality of more than two per cent. is not due to the disease *per se,* but in most instances to too early, too radical, and injudicious interference generally by the medical or surgical attendant. It is better to have a live patient with a draining sinus than a dead one with the chest closed. Above all, keep them alive.

Pneumonia with Special Reference to Diagnosis and Treatment.—In the majority of cases the diagnosis is easy; a sudden onset of illness, pain in the side, cough and fever, rusty sputum, and leucocytosis spell pneumonia. In young children and senile persons the diagnosis is often difficult. It is also difficult when pneumonia develops as a complication during the course of some other malady. David Riesman (*Medical Clinics of North America,* November, 1924) points out some of the errors and some of the ways of avoiding them.

Quite often in children, but by no means infrequently in adults one sees cases that start out as pneumonia, with chill and high fever, but with little or no cough, and without definite signs in the chest. These are probably cases of central pneumonia. Careful examination usually reveals some change in the pulmonary physical signs, especially in spots near the angle of the scapula and in the axilla. Percussion may show changes over a spot perhaps not larger than a silver dollar. The note is a little shortened rather than dull. The breath sounds are muffled or suppressed, and a few fine râles are usually heard on coughing; the voice will have a twangy quality. In addition, an expiratory grunt justifies the diagnosis of pneumonia. A high leucocyte count is a valuable corroborative sign, but is not always present.

The most confusing cases are those which begin with abdominal symptoms. It is a good rule not to make a diagnosis of acute appendicitis or other acute abdominal disease until pneumonia and pleurisy are excluded, especially if the leucocytes in a suspected case of abdominal disease are above 20,000.

Postoperative pneumonia may not present typical signs and symptoms. There may be no cough and no pain of particular severity, only a little fever and increase in respiration rate. The lesion is rarely in front. It follows more often upon abdominal than upon pelvic operations. Pneumonia may also resemble typhoid fever, meningitis, pleurisy, tuberculosis, pulmonary infarct, pulmonary congestion, acute pericarditis, and pyelitis.

In the pneumonia of children, the following points need emphasis: 1. Lobar pneumonia is more common in infants and children than the textbooks teach. 2. The physical signs of primary lobar pneumonia are at times late in appearing. The combination of high fever with leucocytosis is suggestive. 3. The signs may be apical or basal; sometimes they appear first in the axilla. 4. An expiratory grunt is very suggestive. 5. Convulsions, delirium, and meningeal symptoms are common in the pneumonia of young children. 6. Abdominal symptoms, pain, tenderness, and vomiting are often present and mask the pneumonia. 7. Lesne's scalene sign may be of value. It consists in immobility of the subclavicular region due to contracture of the scalene muscles on the side affected. 8. Empyema is a frequent termination, and manifests itself by continuing fever, pallor, sweating, etc. 9. Primary lobar pneumonia in children is a very benign disease; even if empyema develops, the prognosis is good, with proper treatment.

Endocarditis is surprisingly rare in pneumonia, but myocardial change is common. Abnormalities in rhythm are not common, but auricular flutter and fibrillation have been observed. Digitalis may lead to arrhythmia. The so-called Gibson rule, namely, that when the blood pressure expressed in millimetres falls below the pulse rate so that the two cross, the prognosis is bad, is not without exception.

The preventive treatment of pneumonia is not yet fully established.

The curative treatment divides itself into specific treatment, general treatment, and treatment of complications.

Specific treatment is of five types: 1. The use of serums from immunized animals is available only in pneumonia due to Type I pneumococcus, but even this is not an ideal specific. Antipneumococcus serums must be given as early as possible, intravenously, and in large amounts. The danger of anaphylaxis may be avoided by preliminary desensitization with injections of adrenalin. Serum sickness very frequently follows and is a most depressing sequel. 2. The use of serum from convalescent patients has been abandoned. 3. The use of chicken blood and chicken blood serum has shown some good results, but it is a questionable agent. 4. The results with extracts or antibodies from the pneumococci themselves have not been brilliant. 5. Chemotherapy includes quinine and mercurochrome. The former does not rank as a specific in human infection. Optochin (ethylhydrocuprein) is an unsafe drug. Mercurochrome has given good results in streptococcus pneumonia. Cold air treatment, if applied in all cases, does harm. It should be used only in patients that are vigorous. Diathermy has also been recommended.

In the general treatment, aside from the uncertain specifics mentioned, toxemia is best lessened by diuresis and keeping the bowels open. The best diuretic is abundance of water, enough to produce fifty to seventy ounces of urine a day. The following rules should be followed: The less handling the better; no sponging except in unusual cases; no company; icecap to the head, and alkalinization of the patient. Urinary retention should be avoided. The diet should consist of cooked cereals, fruit juices, milk or buttermilk, poached or soft boiled egg, junket, plain custard, wine jelly, water ice. If there is nausea, ginger ale, or charged water is given. Myocardial failure is best avoided by giving digitalis from the beginning in any patient who is decidedly ill. For developing pulmonary edema, give atropin, grain 1/75, repeated in two hours if necessary; digitalis hypodermically; caffeine sodium benzoate and camphorated oil. Dry cupping may be useful. For marked cyanosis with or without pulmonary edema, venesection is indicated and perhaps the use of oxygen. Tympany requires external application of turpentine stupes, the rectal tube, asafetida enemas, and pituitrin hypodermically. Insomnia is best controlled by bromides or morphine. Distressing cough must be combatted with codeine or morphine. Alcohol seems to be of great value in septic pneumonias and in alcoholics. In children, the flaxseed poultice is valuable.

The causes of delayed resolution are the following: failure of proper liquefaction of the exudate through a lack of ferments or an excess of antiferments; empyema, abscess of the lung, tuberculosis, pericarditis, syphilis, arthritis, otitis media, perhaps hepatitis, and residual edema.

The pneumonia patient requires at least two weeks to recuperate under supervision.

Experimental Production of Pneumococcus Pneumonia in Mice by the Inhalation Method.—Ernest G. Stillman and Arnold Branch (*Journal of Experimental Medicine,* December, 1924) conclude from animal experiments that nonimmune mice which are alcoholized and die of septicemia following exposure to a spray of virulent pneumococci rarely show any localization of infection in the lung. Mice partially immunized by previous inhalations of living or killed pneumococci and which while alcoholized are exposed to an atmosphere of virulent pneumococci often develop a pneumococcus lobar pneumonia. Mise which have been rendered relatively immune to one type of pneumococcus may frequently develop lobar pneumonia after the inhalation of pneumococci of another type.

Pathology of Experimental Pneumococcus Pneumonia in Mice.—Arnold Branch and Ernest G. Stillman (*Journal of Experimental Medicine,* December, 1924) state that lobar pneumonia in mice is not of strict anatomical distribution, the infection spreading in the interstitial tissue like any other cellulitis. Following inhalation of pneumococci the organisms are not visible histologically in the lungs of mice, either in the bronchi or alveoli. The administration of alcohol produces no evident histological changes in the lungs of mice. In partially immunized mice which have been exposed to a pneumococcus spray while alcoholized, true lobar pneumonia not infrequently develops.

Relation of Chloride Metabolism to Toxemia of Lobar Pneumonia.—Russell L. Haden (*Journal of Laboratory and Clinical Medicine,* February, 1925) says that the observations reported are based on the study of seven cases during an acute lobar pneumonia. In all, the blood chlorides were below the normal level. In five, the nonprotein nitrogen and urea nitrogen were above the upper level of normal. Two patients died, and in the other three, the nonprotein nitrogen and urea nitrogen returned to normal as the blood chlorides reached the normal levels. The urine chlorides were very low in all cases. One patient was treated with sodium chloride, being given 152 gm. of salt by mouth, besides that taken in with the food. Haden states that the changes observed are probably due to a generalized protein destruction. The administration of the missing chloride seemed to influence markedly the course of the disease. In all cases of lobar pneumonia, sufficient chloride should be given to keep the blood chlorides at or near the normal level.

MALIGNANCY

Marked Structural Alteration in a Breast Carcinoma Recurring After Eleven Years.—Edward M. Hanrahan (*Bulletin of the Johns Hopkins Hospital,* February, 1924) describes a case diagnosed as Paget's disease of the breast, which recurred eleven years after operation. The morphology of the recurrence is the chief point of interest, as the tumor presented malignant transformation of the stroma or very marked alteration of epithelial cells. The transformation of the morphology of the tumor is discussed.

Inflammatory Carcinoma of the Breast.—B. J. Lee and N. E. Tannenbaum (*Surgery, Gynecology and Obstetrics,* November, 1924) from a survey of a number of cases, conclude that inflammatory carcinoma appears to be a distinct clinical phase of carcinoma of the breast. Generally this type has been unrecognized, being frequently mistaken for other diseases of the breast. The inflammatory appearances are characteristic. This variety of mammary cancer shows no constant pathological type. The most striking pathological change is a wide invasion of dermal lymphatics by carcinoma. Bacteriological and biochemical studies have failed to explain the inflammatory manifestations. The cases do badly if treated surgically. At present radiation offers the only hope of palliation, diminishing the patient's suffering, and giving a definite prolongation of life.

Cancer of the Thyroid.—J. L. Decourcy (*Annals of Surgery,* October, 1924) has observed that cancer of the thyroid is rarely primary, but it develops in practically every case in adenomata of years duration. This at once suggests that cancer of the thyroid could be eliminated in great part at least, by the early removal of all adenomata. All adenomata should be removed as soon as diagnosed. Surgery offers a one hundred per cent. cure in adenomata of the thyroid with a mortality of less than one per cent. in all cases. If toxic, of course, proper judgment should be used as to ligation, time to operate, etc. X ray and radium have no place in the treatment of adenomata, in my opinion, and are more apt to do harm than good. If the above treatment were carried out, cancer of the thyroid would be reduced to a minimum. When cancer has advanced however, to a stage where a clinical diagnosis is possible, then the method of treatment becomes problematical. At present I feel that the outlook is hopeless and that they will do just as well if left alone. I may be wrong. I do not, however, believe that surgery is indicated. Possibly needling with radium, at present offers the best means at our disposal. Deep x ray therapy may find its place in the treatment of thyroid cancer but I feel that it may do damage in the destruction of the parathyroid bodies. The technic for needling with radium is as follows: The wound is opened and the muscles separated as in the first step of a thyroidectomy. The needles are then inserted into one lobe of the mass, each needle being about one half inch apart. The wound is left open and the needles removed in twelve hourse, the following morning, or twelve hours later the wound is closed. The patient is then kept under observation for four weeks. Usually after two or three weeks the mass becomes edematous and there is some danger of strangulation. About the fourth week the other lobe is needled. This treatment should be followed by a prolonged course of x ray therapy.

Virulence Test and Operative Mortality in Carcinoma of Cervix.—The investigations of E. Bumm (*Zentralblatt für Gynäkologie,* September 13, 1924) with the Ruge-Philipp virulence test have shown that in ten per cent. of the patients with operable carcinoma of the cervix virulent germs are found in the vagina. Operation in these cases is associated with great danger, in spite of a careful technic, as severe infection usually follows. Germ virulence has the same significance in the radium treatment of carcinoma. This virulence of germs has an extraordinary significance also in obstetrics, particularly in Cæsarean section.

In order to eliminate this danger the author makes use of local disinfection. The ulceration is first cauterized, then washed with sublimate alcohol and, finally, silver nitrate is applied on packing. This form of treatment has given good results. However, this treatment destroys only the germs that are on the surface, not those lying more deeply. Streptococci and grippe excitants are particularly resistant to treatment. Even the production of an increased resistance of the body has not been found successful. Therefore, there remains nothing but the avoidance of operative procedures. Radium treatment is preferable in such cases.

Malignant Epithelial Tumors of the Thyroid.—A. Graham (*Surgery, Gynecology and Obstetrics,* December, 1924) offers the following conclusions to his investigations: At least ninety per cent. of malignant tumors arising from thyroid epithelium have their origin in preexisting adenomata. The morphological character of the cells and tissue is an unreliable basis for the determination of malignancy of thyroid epithelial tumors. The malignancy of thyroid epithelial tumors depends upon their tendency or capacity to invade the capsule, surrounding tissue, lymphatics, or blood vessels. The most constant single indication of thyroid epithelial malignancy is invasion of the bloodvessels. Scirrhous and papilliferous adenocarcinomata are the only two types of epithelial malignancy in which invasion of the bloodvessels has not been observed. These two types together constitute about fifteen per cent. of the total and are primary lymphatic invaders. Epithelial tumors that are encapsulated and show no invasion of the bloodvessels are benign, irrespective of their microscopic appearance otherwise. Epithelial tumors in which one finds invasion of the blood vessels cannot be regarded as entirely harmless, irrespective of their microscopic appearance.

The term carcinoma is proper for epithelial tumors of the thyroid that are malignant regardless of their microscopic appearance. The term malignant adenoma is useful and convenient for the purpose of denoting a subgroup under carcinoma but is not, strictly speaking, correct terminology. Such terms as *wuchernde struma,* proliferating adenoma, metastasizing adenoma, metastasizing colloid struma, metastasizing colloid goitre, and metastasizing normal thyroid are confusing, misleading, inaccurate, serve no useful purpose, and should be eliminated. In view of the present available data the diagnosis and classification of malignant epithelial tumors of the thyroid present no greater difficulties and require no more complicated nomenclature than is commonly encountered in other organs and tissues of the body.

Medicolegal Notes.

DEATH FROM ERYSIPELAS FOLLOWING VACCINATION HELD NOT COMPENSABLE

The Illinois Supreme Court holds, Jefferson Printing Co. v. Industrial Commission, 312 Ill., 575, 144 N. E. 356, that death from erysipelas following vaccination was not compensable as due to an accident arising out of the employment, where the record failed to show any susceptibility to the infection of erysipelas peculiar to the work in which deceased, a printer, was engaged, or incidental to the business of his employer.

TYPHOID FEVER FROM DRINKING POLLUTED WATER DUE TO DEFECTIVE VALVE HELD ACCIDENT

The Illinois Supreme Court holds, Christ v. Pacific Mut. Life Ins. Co., 312 Ill., 525, 144 N. E. 161, that the death of a railroad employee from drinking water from pipes containing polluted water due to a defective gate valve intended to separate the drinking water from the polluted water, resulting in his contracting typhoid fever, was caused by "external, violent and accidental means" within an insurance policy. (231 Ill. App. 439 affirmed.)

ROYALTIES ON MEDICAL WORKS HELD PARTLY PRINCIPAL AND PARTLY INCOME

A controversy arose in the settlement of a physician's estate as to whether royalties on a medical book of which he was the author constituted principal or income. The New York Appellate Division holds, In re Elsner's Will, 210 App. Div. 575, 206 N. Y. Supp. 765, that the property represented by the contract and the royalties should be apportioned between capital and income, in view of section 204 of the Surrogate's Court Act and also because the practice has long been recognized and adopted in analogous cases, both in New York State and other jurisdictions. The court said: "Such funds partake of the nature both of principal and income. The original principal or capital was the book itself, a creation of the skill, experience and learning of the author. The book might have been sold directly to the publisher either for a definite sum payable immediately, or by installments for a period of years. In either case, the principal would then be the sum of money thus received, substituted in place of the original capital, the book. This sum, if invested, would produce income. But the author preferred to take a speculative contract to effect a sale, whereby he received a percentage of profits to continue as long as the book met with favorable sale. The principal is, under these circumstances, the beneficial interest the author had in this contract—its present value as a producer of income. It would be a simple question if the principal remained unimpaired in value. Its earnings would be income. But it is common knowledge that professional works are books of a period and their profitable life limited in time. Progress in the particular science concerning which they treat opens new and interesting fields of research and discovery. Almost invariably later books by other authors containing the new learning thus acquired supersede the older books. Their sale declines and vanishes. This is obviously the experience of this book, which produced royalties of nearly $4,000 in 1916, and but $13.50 from July 1, 1922, to December 31, 1923.

ANSWERS TO QUESTIONS AS TO INSURANCE APPLICANT'S HEALTH

The Oklahoma Supreme Court holds, Security Benefit Assn. v. Green, 229 Pac. 1061, that if the applicant for life insurance truthfully states the facts to the agent pertaining to the questions being asked him about his health, and the agent who is authorized to ask the questions and write the answers deduces erroneous answers and writes them into the application, the beneficiary will not be prevented from showing the true facts of the insured's warranty. In an action by the beneficiary for recovery on the policy, the court holds that the insurance company will be estopped to set up the erroneous answers as false representations by the insured to defeat recovery.

EMPLOYEE'S STATEMENTS AS TO ORIGIN OF DISABILITY

An employee's statements to physicians several days after an accident ascribing the origin of his disability to his daily work, were inadmissible under the hearsay rule, and did not become competent because of the subsequent death of the employee.—Ross Case (Me.) 126 Atl. 484.

APPENDICITIS FROM BLOW ON ABDOMEN

The Washington Supreme Court holds, Clark v. Department of Labor and Industry, 230 Pac. 133, that appendicitis entitled claimant to compensation where the evidence showed that it resulted from a blow on the abdomen from one of a number of blocks claimant was sorting, medical testimony for claimant, including that of the physician who treated her, being to the effect that appendicitis can be superinduced by trauma, although the chief medical officer was of opinion that appendicitis does not result from accident.

PROOF INSUFFICIENT TO SHOW TRAUMATIC HERNIA

The New Jersey Supreme Court holds, Rosario v. Heller Bros. Co., 126 Atl. 294, that where the proof fails to indicate any puncturing or tearing of the abdomen wall or any prostration there is no proof of a traumatic hernia under the Workmen's Compensation Act.

REFUSAL TO HAVE OPERATION PERFORMED

The Maine Supreme Judicial Court holds, Beaulieu's Case, 126 Atl. 376, citing Ruabon Coal Co. v. Thomas, 3 B. W. Comp. Cas. 32 to the effect that whether or not a workman is unreasonable in refusing to have an operation performed is a question of fact in a Workmen's Compensation case, with which an appellate court will not interfere where the doctors are not wholly agreed as to the advisability of the operation, holds that, where the Chairman of the Maine Industrial Commission's finding that the claimant had not unreasonably refused to submit to proper surgical treatment was justified by the evidence, the doctors and surgeons being at variance as to the exact nature of the treatment which should be tried, and all practically admitting that any operation would be followed by great pain and inconvenience, and that the results of any treatment would be uncertain as to permanently successful results, a petition to discontinue compensation was properly denied.

QUESTION TO MEDICAL EXPERT AS TO COURSE OF BULLETS HELD ADMISSIBLE ON CROSS EXAMINATION

The Alabama Court of Appeals holds, Jones v. State, 101 So., 331, that a question asked a medical witness for the defendant in a shooting case, on crossexamination, as to whether the bullets could have ranged upward if deceased had been standing, was legitimate on cross examination in testing the knowledge of an expert witness.

Repair of Inoperable Soft Palate by Utilizing the Faucial Tonsils*

J. EASTMAN SHEEHAN, M.D.,

New York

I wish to bring to your notice a method by which, in three otherwise inoperable cases, the resources of plastic surgery were drawn upon to effect, by the use of the adjacent palatal, tonsillar and pharyngeal tissues, a repair of total cleft palate conditions, the result of which was to provide a soft palate that functioned with considerable efficiency. The method is still experimental, but the results justify the expectation that the relief desired can be afforded with increasing assurance of certainty as observation of results conduces to technical improvement. Complete success would, of course, eliminate the characteristic cleft palate deficiency in regard to speech. Notable improvement was effected in the three cases described.

The palate as you know is a mucomuscular fold. The fact suggests, when the palate is absent, the use of like materials, if such are available, for its replacement. Such materials are present in the adjacent muscular and faucial tonsil areas. The problem consists in utilizing the needed tissues to construct a new palate, and still leave the muscles with capacity for exercise of their functions, particularly upon the new palate itself, in the way they would function if conditions were normal.

An essential to success is the provision of an epithelial covering for the areas of excision, to obviate the destructive tendency of the contractures that would supervene if this precaution were not taken.

The function of the palate is to close off, completely or partly, the nasal chambers from the oral pharynx. The exercise of this function is of particular importance in relation to speech, for the palate, like the tongue, the lips and the teeth, has a definite part to play in modifying the fundamental voice sound, originating in the cords of the larynx, differentiating the vowels and consonants, and making possible those modulations which account for the formation of words and hence the habit of articulate speech.

In the enunciation of the nasal consonants (m, n, ng sounds) the normal mobile (soft) palate moves very slightly, if at all, towards the pharynx; whereas in the definition of the mixed nasal and oral consonants (the harsh aspirate sounds of x, k, y, z), the palate approaches the pharyngeal wall. Where the pure tone of the vowels is to be obtained, the palate closes off the nasal cavity altogether, and the sound proceeds through the mouth, issuing from the lips. It follows that when the velum is absent, and the sound from the larynx is not exposed to its control, the tongue, teeth and lips are not able to subject the fundamental tone to all the necessary modulations, and from this failure to differentiate and define there results that inarticulate incoherence unmistakably recognized as the cleft palate defect of speech.

In what concerns deglutition, it is well not to lose sight of the fact that where there is a palate the first action on swallowing consists of pressure of the morsel against the palate by the tongue. The levator and tensor muscles also operate in close coordination with the muscles of the pharynx in effecting the downward passage of the food. Restoration of the palate is therefore distinctly a service in this regard.

In many attempts to cover the defect left in cases of total cleft palate, the membranes of the pharynx, of the tonsil, and over the velar eminence have been utilized. When these membranes were brought up from both sides and joined, there was produced a bar which occupied the place of the palate, and which conduced to improvement in the control of some of the consonantal sounds, but in the rest of the field there was no control, the general result being therefore unsatisfactory. It could not be otherwise, as in this method of repair either allowance was not made for the function of the normal velum or the attempt was not made to extend the mechanism of voice control into that area where it is affected by normal velum.

What was left to be attempted, therefore, was the building up of a soft palate by utilizing the faucial tonsil and the muscles which surround it. In the three cases under review, in which this was done, the patients were all adults. Each of them had already undergone several operations, and had been assured that the relief desired was not procurable. Further resort to the membranes from velar areas was precluded by the circumstance that not enough was left of them to justify the expectation of success.

A study of the anatomy of the soft palate reveals that, of the muscles composing or entering it several have considerable extension beyond the palate, and that most of the fibres are in fact away from it rather

than of it. The most important of these, for the present purpose, are:

1. The palatopharyngeus, a long fleshy fasciculus, forming, with the mucous membrane, the posterior pillar of the normal soft palate. Passing outward and downward behind the tonsil, it joins the stylopharyngeus, and is inserted with that muscle into the posterior border of the thyroid cartilage. Its function is to approximate the pharyngopalatine arches, and to elevate the inferior parts of the pharynx and larynx, thus closing the posterior nares and faucial orifice.

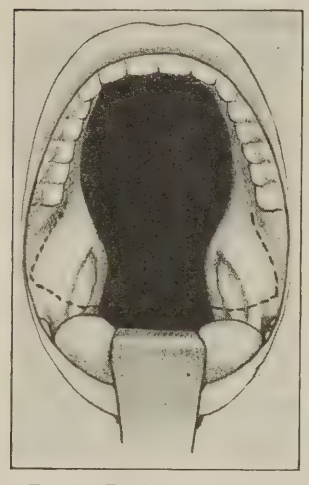

Fig. 1.—Total cleft palate with pharyngeal and tonsillar areas.

2. The palatoglossus—an important muscle this—and a small fleshy fasciculus, arising from the anterior surface of the soft palate next the uvula, forming, with the membrane, the anterior pillar of the soft palate. It passes downward, forward and outward in front of the tonsil and is inserted into the side of the tongue. Its function is to narrow the faucial isthmus and to raise the back of the tongue.

3. The superior constrictor, which rises from the palate bone, the internal pterygoid plate, the pterygomaxillary ligament, the alveolar process of the jaw and the side of the tongue. It is inserted into the posterior median raphe of the palate. It contracts the pharynx, e. g., in the act of swallowing.

4. The salpingopharyngeus, which arises from the eustachian tube and descending blends with the palatopharyngeus. Its function is to raise the nasopharynx.

5. The levator palati, which arises from the eustachian tube and the temporal bone, passes into the pharynx above the margin of the superior constrictor, and, descending obliquely, is inserted into the soft palate as far as the middle line. Its function is to raise the soft palate.

6. The sixth and last muscle which concerns us is the tensor palati, which, arising from the scaphoid fossa at the base of the pterygoid plate, ends by insertion in the palatal aponeurosis, and so may be present in the area of dissection. Its function is to stiffen the palate.

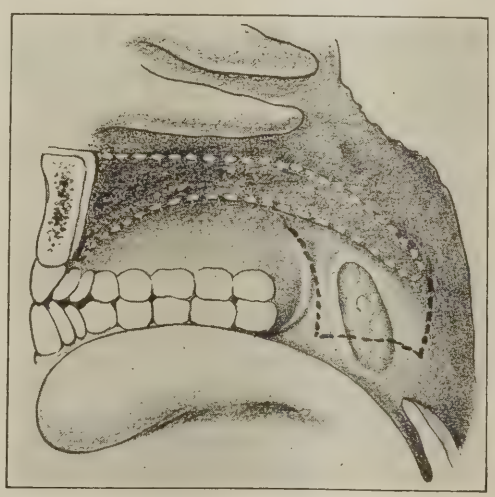

Fig. 2.—Normal palate in white outline; area of replacement flap in black outline.

It is obvious that in the abnormal situation due to the absence of palate, into which all of these muscles except the superior constrictor would be inserted, a considerable amount of distortion must be expected in their relations to the area nearest the palate. To dissect them with accuracy and to fit them into relations which would restore their functions completely would be too much to expect. But where they are all included in the muscle flap of which the new palate is made, it is not too much to expect that their functions will be stimulated to a percentage of efficiency.

These muscles, lying in the same field, present to the surgeon an opportunity for separating from the surfaces of the pharynx and tonsillar areas, on both sides, amounts of tissue adequate to form a substitute for the missing velum. A goodly portion of the faucial tonsil is brought up with the muscle, to give greater bulk to the palate, and also with a view to providing some substitute for the uvula. The flaps so separated are swung up to the median line, the distal ends are joined, and the palate so formed is connected with the important muscles, especially the palatopharyngeus.

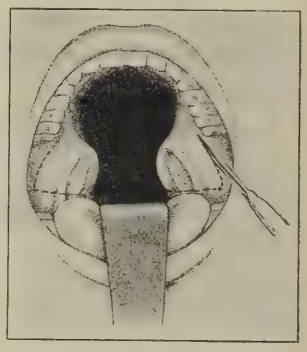

Fig. 3.—Initial incision.

In time the palate so constructed establishes functional relations with the contiguous muscles, and once this occurs the new organ responds to the natural demand upon it as a normal constituent in the economy of the mouth and throat.

In the procedures for lifting these flaps of muscle and tonsil the bleeding is likely to be severe, and ample precaution must be taken to ensure adequate control.

It will be remembered that the tonsils are in relation with five sources of arterial supply. 1. The ascending pharyngeal branch of the external carotid; 2 and 3, the ascending palatine and the tonsillar branches of the facial; 4, the tonsillar branch of the dorsalis linguæ; 5, the descending palatine branch of the internal maxillary. Some anatomists claim also the presence of a small twig from the meningeal. Ordinarily these branches are small, but sometimes they are large and may cause troublesome bleeding.

If the bleeding is arterial the bleeding points should be identified, clamped and tied. This is best accomplished by the use of a long curved hemostat, which has recently been put on the market, the inventor being Mr. H. Bedford Russell, of London. For the general ooze, which is usually venous, but may be from the small arterials, pressure is exerted in the faucial cavity by the use of gauze or the moulded stent; or the pedicled tonsil may be reinserted and held in place until the bleeding is controlled.

If the arterial bleeding is smart and the bleeding points are not identified, pressure is applied to the

carotid artery, using a key or other blunt instrument, externally to the neck, as the full blood supply of the tonsil is from that artery. This facilitates a closer inspection and the identification of bleeding points. Release of the pressure will indicate whether all have been cared for.

If the tonsils are diseased, should it be considered a

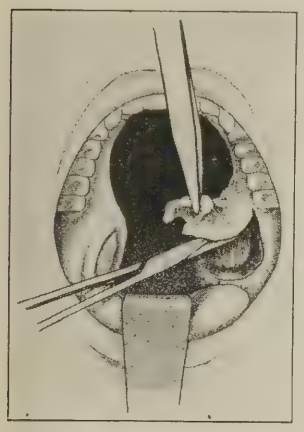

FIG 4.—Flap lifted after deep separation.

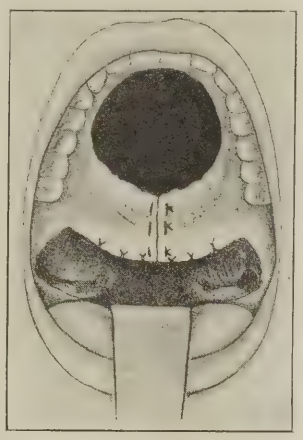

FIG. 5.—Flap joined, forming soft palate.

contraindication? In one of the cases under review the tonsils were infected. It was a question whether one should risk including such material in the flaps, but the condition made it desirable to take the risk, and as it turned out the portion elevated became normal in its new relation, whereas the portion left *in situ* continued infected and subject to inflammation.

Where the tonsils have been excised, it should not be regarded as a contraindication. The muscle flap can still be brought up, but it will not make quite as good a palate. In the three cases here described the tonsils were present.

The upper point of the incision is well above the superior horizontal line of the faucial tonsil. The incision is carried well toward the cheek, thence directly downwards across the tonsil, to include its upper two thirds, then backward over the posterior pillar, to include about a quarter of an inch of the pharyngeal membrane, then up to a level with the original point of incision. The edges of the flap to be brought up are thus outlined. The muscle, membrane and tonsillar tissue within these borders is then deeply separated, by the use of a long semicurved scissors with blunt ends.

The flaps are now drawn up for suture along the median line.

Beginning at the back, the needle enters about an eighth of an inch back from the free membranous border, and is then carried back until it includes a generous portion of the muscular filaments which form the posterior pillar. It is then brought out and carried to the opposite side, where the order is reversed, the needle first entering the muscles of the posterior pillar, then forward to the membranous border and out. The suture is now tied, thus forming the first stay of the palate in its new position. The tonsillar materials from the two sides are joined with three mattress sutures, the membranes of the anterior pillars are brought together in the same way as those of the posterior areas, the suture passing through the palatoglossal muscle to establish the stay on this side.

The surface of the new palate is now established by bringing together, underneath, the membranes from front and back, which are joined with several horsehair sutures.

These procedures are carried through under combined local and general anesthesia. Novocaine, one per cent. solution, is used for blocking the local nerves. General anesthesia is obtained by intertracheal insufflation of ether. The local blocking affords a relief to the brain from the afferent impulses that may otherwise conduce to shock and exhaustion, while the insufflation method permits the packing of the larynx with gauze, thus preventing the passage of blood into the lungs. By this method, also, the amount of ether to be used can be most accurately controlled.

Attention must now be given to the raw areas, which if left to heal of themselves would develop contractures destructive of the newly formed palate. Since they cannot be left to epithelize of themselves, the recourse is to supply a lining by means of a Thiersch graft.

Previous to the operation, the patient is referred to a dentist, who makes, and attaches to the upper teeth, a denture so designed that it will allow free control of a movable bar, at the other end of which is a splint to carry a moulded stent.

With the heated modelling compound attached to this splint a mould is taken of the raw area to be covered. Over this mould, when it has cooled, the Thiersch graft is placed, raw surface uppermost. The graft is made large enough to overlap the back of the stent; there it is sutured or tacked into position. Then, by moving the bar, it is brought into the desired position, the graft now being in contact with the raw area.

This has to be done for both sides. The denture will therefore provide for two movable bars, two

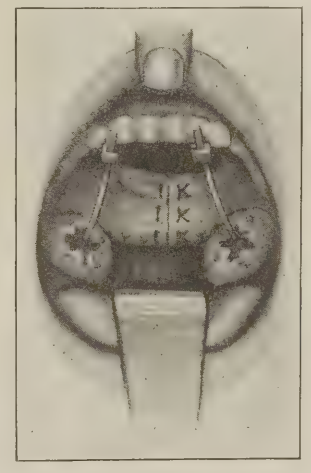

FIG. 6.—Thiersch grafts held in place by moulded stents over denuded areas.

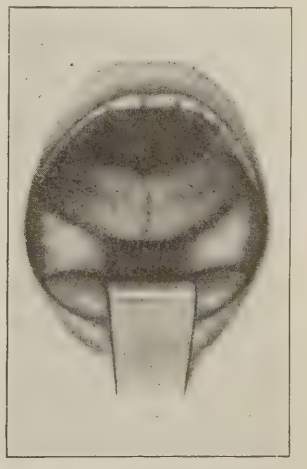

FIG. 7.—New soft palate in place; hard palate later replaced with obturator.

stents, and so for two Thiersch grafts, one for each side.

The Thiersch graft is cut from the inner aspect of the right leg, in the nonhairy area.

The graft is held in position for from eight to ten days, after which it is removed. Nothing is allowed

to enter the mouth for three days after removal of the stent. This gives a chance for any raw area to epithelize. In time contractures may develop, but not to such an extent as to injure the newly made palate.

Two or three days before the operation, the mouth is thoroughly cleansed, the teeth with ivory soap four or five times a day. Witch hazel is used as a gargle. Suction is applied daily to the faucial tonsil to remove any infected debris that has collected in the crypts.

A day before the attempted repair an Einhorn duodenal feeding tube is inserted through the nostril, and passed down through the esophagus and stomach to the duodenum. It is obvious that nourishment cannot be given by the mouth, and this method is better than per rectum.

The diet consists of 240 c. c. of milk, one raw egg and fifteen grams of sugar of milk, well mixed and beaten, administered at blood temperature. The flow through the tube is sustained by the use of a large glass syringe. The food is given every two hours from 8 a. m. to 8 p. m. At intervals during the day a small amount of water is given slowly. Physiological salt solution is injected per rectum by the Murphy drip method; 350 c. c. in the morning and again in the late afternoon. The first two or three days the patient is restless and uncomfortable. To curb this condition one quarter grain codeine sulphate, frequently given, is allowed to dissolve under the tip of the tongue, this being equivalent to hypodermic injection. The mouth is kept rigidly clean, the nurse swabbing at frequent intervals with one of the several mouth washes. Weak solution of potassium permanganate is to be recommended. The nurse will also scrub the teeth several times daily with ivory soap. If the patient becomes constipated it is well to inject through the tube a little magnesium usti, as much as will cover the tip of a knife.

This treatment continues until three or four days after the removal of the stent.

In the cases treated the temperature never rose above 101°, and this was only temporary.

The defect in the hard palate remains to be dealt with.

In the three cases cited, obturators were applied. It would be feasible, however, to use full thickness skin, to the under side of which a lining had been applied by Thiersch grafting. This has been demonstrated by Coughlin of St. Louis. It was suggested to one of the three patients, but he was content to have the obturator and be relieved of further surgical procedures.

Where the palate has been replaced, as in the operation described, the patient should be recommended to an expert in speech training; the results are both immediately and permanently better than if the patient tries to work out unaided his system of vocal production.

636 Fifth Avenue.

A Further Study in Blood Chemistry and the Results of Ultraviolet Ray Therapy in Certain Tuberculous and Other Cases*

FRANK A. DAVIS, Sc.D., M.D.,
Boston

In a paper read before the Academy of Physiotherapy in New York City in September, 1924, in which the use of physiotherapy in the treatment of tuberculosis was discussed, and in which was included a report on certain laboratory findings made under my supervision for the purpose of determining the probable physiological action of the ultraviolet rays on blood chemistry, the following tentative conclusions were presented:

1. That, in most instances, the action of the rays nas a tendency to increase the calcium content of the blood in those exposed to their influence. This conclusion coincides with the opinion of other investigators.

2. That, where exposure is continued over a considerable length of time, marked pigmentation and thickening and scaling of the skin usually takes place.

3. That, in those cases where pigmentation, thickening and scaling of the skin take place, the hemoglobin of the red blood cells is usually decreased, but that the red cells have a tendency to increase in number, thus maintaining a balance in the physiological function of the blood.

4. That pigmentation of the skin results from elements deposited in it from the hemoglobin, and that pigmentation and thickening of the skin is nature's method of defense against undue blood chemistry changes in those subjected to prolonged exposure to ultraviolet ray influence.

5. That the coagulation time of the blood is decreased in those exposed to the ultraviolet rays, which is undoubtedly due to an increase in the calcium content of the blood. This is of particular interest in cases requiring operation, or where hemoptysis may occur.

6. That the use of radiant light and heat should be avoided in tuberculous patients, either before or after ultraviolet ray exposure. Heat stimulates general and lymphatic circulation, and promotes metastasis. It also has a tendency to break down protecting adhesions. Personal observation has shown this to be true.

7. That the treatment of tuberculous sinuses by means of the water cooled quartz lamp, in socalled surgical tuberculosis, is usually of little permanent benefit. This is due to the limited and local action of the rays, coating of the rod applicators by the discharges from the sinuses, and also due to the fact

*Read before the Academy of Physiotherapy, Atlantic City, May 25, 1925.

that the disease at this time is more constitutional than local. In these cases the general application of the rays from the air cooled lamp has given me far better results, and with less trouble and less discomfort to the patient. The water cooled lamp has been found efficacious in many cases of superficial ulcer, whether tuberculous or otherwise, the pressure method being used, with an initial exposure of one to two minutes, as the case seems to indicate, a local reaction from the exposure being the objective sought. The surface of the ulcer should first be made clean and dry.

8. That, in the treatment of adult tuberculous patients by heliotherapy, discriminating care should be used with reference to the intensity of the treatment and the general effects of the sun's heat upon the circulation and the patient's general condition. Differentiation should also be made between heliotherapy and out of door life. Altitude and latitude should also be considered.

Recent and further laboratory examinations, which I have had made in connection with ultraviolet ray influence on blood chemistry, have served to strengthen the conclusions referred to, and to lead me still further along the same general lines of thought. In this connection, I have come to feel that in advanced life, where cardiovascular changes have taken place, and hypertension is manifesting itself, the use of the ultraviolet rays may be inimical to the patient's welfare, and that, before such treatment is instituted, a careful blood chemistry examination should be made. If the calcium content of the blood is found above the normal, it is my belief that ultraviolet ray therapy in contraindicated. The average normal calcium content appears to be about 11 mgs. to 100 c.c. of blood serum, although 10.5 to 11.5 mgs. may be considered within the normal range so far as therapeutic indications are concerned.

Reasoning along similar lines, it would appear that ultraviolet ray therapy may be beneficial in certain cases of acidosis where the normal alkali base of the system is disturbed on the negative side.

Some writers maintain that the lymphocytes are increased in those exposed to the ultraviolet rays. My investigations, thus far, have not led me to this conclusion. Individual cases sometimes show this tendency, but the cause is apparently due to the underlying pathology rather than to ultraviolet ray influence. Tuberculous patients usually show a leucocytosis whether exposed or not exposed to the ultraviolet rays.

The blood nitrogen and uric acid in these cases are usually high during the period of hospitalization; but this is the result of the physical inactivity which is enjoined upon patients as a part of their treatment, and indicates a lowered nitrogenous waste elimination resulting from lessened metabolism, rather than ultraviolet ray action on blood chemistry. When this condition becomes troublesome and toxic symptoms manifest themselves, I have found that mild autocondensation treatments are frequently of benefit if given in alternation with ultraviolet radiation. These treatments should not exceed 150 to 400 milliamperes, given for a period of twenty minutes. The patient's physical condition should serve as an index of the intensity of the treatment, but in no case should the intensity be great enongh to render the patient conscious of increased body heat. This prevents harmful lymphatic stimulation.

Undoubtedly, other blood chemistry changes take place under ultraviolet ray influence which serve to affect the physiological processes of the body. This is particularly true of the phosphorus bearing elements, but, thus far, I have not been able to investigate this field. From experience and observation, however, I feel convinced that in many cases, where there is an excess elimination of the phosphorus compounds, that ultraviolet ray therapy will help in correcting the condition.

The blood chemistry changes resulting from ultraviolet radiation take place principally in two ways: First, through absorption of radioactivity from the rays by the red blood cells while circulating near the surface of the body upon which the rays are falling, and thus, by means of those cells and the blood stream, carrying radioactivity to the cells, and in this manner stimulating or inhibiting the hormone function of certain glandular structures, as the case may demand. Second, through the influence of the rays upon the cutaneous nerve endings, the sympathetic nervous system, through reflex action, is undoubtedly caused to play a part in the automatic regulation of the physiological activties of the laboratories of the body. In both cases the ultimate results appear to influence physiological processes rather than directly influencing the blood itself. These processes are probably analogous to those which take place in the chlorophyl of the leaves of plants, shrubs and trees when they are exposed to the ultraviolet rays given off by the sun.

Under favorable conditions, the bactericidal effect of the ultraviolet rays is marked. Tests made by the Bureau of Standards are reported to have shown that the bacterium coli communis may be destroyed in one second of time when exposed to ultraviolet radiation from a quartz mercury vapor lamp at a distance of six inches. An increase in the distance requires a longer exposure. The water cooled lamp, with its shorter wave length, gave the most pronounced action. In the tests referred to, it is reported that the destruction of the bacteria was proportional to the total exposure, whether given continuously or intermittently.

Scientists state that, were it not for our atmosphere, the ultraviolet radioactivity given off by the sun to the earth is of sufficient power to cause disintegration of all of the earth's minerals within a comparatively short time. Radium is an illustration of such change going on constantly.

Fortunately, the modifying influence of the atmosphere not only prevents undue radioactivity from the ultraviolet rays of the sun, but modifies their physical action so that they perform constructive as well as destructive work. Were is not so, life would disappear from the earth. Vegetable and animal life is a good illustration of the constructive influence of the ultraviolet rays, and of the modifying conditions governing their activity, and shows how well the machinery of the universe is balanced in its efforts to carry on its eternal programme.

But, these modifying conditions are more or less unevenly distributed, and subject to other physical conditions. Clouds, altitude, latitude and longitude all modify the sun's ultraviolet ray activity. Heavy

clouds and common glass prevent their passage. Higher altitude increases their intensity. Varying latitude and longitude increase or decrease their relative activity, depending upon the angle of incidence at which the rays fall. At high noon their influence is greatest. At the equator their influence is direct. To the north or south of the equator their influence will be modified by the angle at which they traverse the atmosphere. This variability in the modifying influence of ultraviolet ray activity accounts largely for the black and brown skinned races of the tropics, and also for the fair skinned races of the temperate zones. It also accounts for many types of animal and vegetable life and their distribution over the earth.

Despite nature's plans, man frequently tries to alter conditions to suit his necessities or desires, and sometimes both. But, when he departs too far from established standards he suffers in consequence. This is particularly true when fresh air and sunshine figure in the equation.

With the discovery of a process for fusing quartz glass, the mercury vapor quartz lamp, both air cooled and water cooled, became possible. At the present time satisfactory models of both types may be obtained from several American manufacturers, and through the therapeutic use of these lamps, ultraviolet ray deficiency may be largely corrected, when intelligent use is made of them for this purpose.

When these lamps were first put on the market their use was often disappointing to both physician and patient, and they came to be regarded with scepticism by a majority of the conservative members of the profession. Even now this attitude is maintained by many. The fault in the beginning was not so much that of the lamps as it was of other factors. Inexperienced enthusiasts and a lack of a proper understanding of the physiological action of the ultraviolet rays were the cause of the larger percentage of failures. Scientific investigation and experience are rapidly changing this state of affairs and are now giving to the lamps their proper place in therapeutics. The empirical use of these lamps is no longer necessary and should be avoided. One should not heed the statements which we often hear that their overuse can produce no real harm. Blood chemistry investigation shows such statements to be untrue.

Were it not for the work involved on the part of laboratory technicians, and the expense to patients in private practice, the ideal way to use ultraviolet ray therapy would be to have a blood chemistry examination made in as many cases as possible before treatment is instituted, and, later, at such intervals as seem necessary in order to check up results. This procedure would prevent many failures.

If pigmentation of the skin is progressive, as a result of ultraviolet ray exposure, it is an index of defense on the part of nature against excessive blood chemistry changes. If pigmentation does not take place after a considerable period of exposure one may rest assured that blood chemistry changes are more or less immaterial and may be disregarded. Pigmentation, therefore, may be used as a partial guide in this respect. A blood count will also help.

Acting along the lines suggested by the laboratory findings referred to, it is now my practice to begin ultraviolet ray treatments by an initial exposure of one half minute to each zone of the body, dividing it into four zones, upper and lower and front and back. This includes the trunk and legs. The eyes should be properly protected, either by colored goggles, or by black paper or pads of gauze or cotton. The average distance of the burner from the surface treated should be about thirty inches in most cases. Each subsequent treatment is increased one half minute to each zone until exposures of five minutes each are given to each zone, or a total of twenty minutes to the entire body. These treatments are given daily, until pigmentation begins to appear, then a change is made to three times weekly, and in some cases the time period reduced to three minutes to each zone. In doubtful cases a blood chemistry examination is made for determining more accurate results. In the case of tuberculous patients, the chest is covered if the condition involves the lungs. This is done to satisfy the minds of doubting tuberculosis specialists, rather than from fear of harmful results.

To illustrate some of the points which I have aimed to bring out in connection with ultraviolet ray therapy, I have summarized the clinical data, and in some instances the blood chemistry laboratory findings, of a few rather interesting cases which have been treated under my supervision during the past six to twelve months, and they are herewith included.

In Cases I, II and III the patients each had tuberculous ulcers in or about the mouth and were treated by the ultraviolet rays from a water cooled quartz lamp. The pressure method was used, beginning with a half minute exposure and increased one half minute daily until reaction occurred. When reaction occurred the treatment was suspended until the acute manifestations had subsided, and then resumed. In some cases reaction took place after the first treatment. In Case I, the patient had a lesion at the left canthus of the lips. At the end of nineteen treatments, all given within one month, the lesion was entirely healed and has remained healed for over eight months. In Case II, there was a lesion at the right canthus of the lips which yielded to fifteen treatments, and has remained healed for several months. In Case III the patient had a lesion on the under surface of the tongue. Healing took place after eleven treatments, and has remained healed for over six weeks.

Case IV.—This patient received treatment from the air cooled quartz lamp over the entire body, beginning with one minute exposure to each of the four zones, and increasing one minute, daily, until ten minute exposures were given to each zone, and were thus continued until twenty-three exposures had been made. The patient had pulmonary tuberculosis, moderately advanced, but without toxic manifestations. The object sought was the reduction of the coagulation time of his blood, preparatory to operation for the removal of his tonsils. He had previously been given calcium lactate by mouth, but unsuccessfully. After two ultraviolet ray exposures his coagulation time was nine and one half minutes. After eight exposures the time had dropped to four and one half minutes, at which average time it remained until the operation. During the operation

he lost less than one dram of blood. The patient stated that he felt better, physically, after the first exposure to the ultraviolet ray.

Case V.—This patient was a colored man, aged thirty-nine. He was in France during the war and had influenza while there. He returned home in July, 1919, and suffered nervous collapse on the way. He went directly to the hospital on arrival, and later he left the hospital and went to work as captain of bell boys in a city club. His normal weight was 130 pounds. After having been at work for some time he began to lose weight, a cough developed, with night sweats and general physical weakness. In July, 1924, he was hospitalized, with a diagnosis of pulmonary tuberculosis. His weight at that time was 108 pounds. On Labor Day he was transferred to our hospital, and later referred to the physiotherapy department for ultraviolet ray treatment. His weight was then 100 pounds when treatment was begun. Previous to his transfer eczema about the face and eyes had developed, and later in the ears and back of the ears. Abscesses had also developed in the ears. There was general excoriation in and about the ears, which was intensely itchy, and accompanied by an irritating discharge and encrustation. Altogether, he presented about as hopeless a condition as one would care to treat with the expectation of accomplishing favorable results.

Treatment was begun with the air cooled quartz lamp; distance twenty-four inches; time, one minute to each side of the head, and increased one minute, daily, until ten minute exposures were given to each area. Improvement began from the first. On January 16th of this year, the ears and face were so much improved that his treatment was changed to three times weekly, and mild autocondensation treatments for his general metabolism were added on alternate days. These treatments were twenty minutes in duration, and a current strength of 400 milliamperes was used. His weight and general condition continued to improve. On February 1st, herpes zoster appeared over the central portion of the right side of his chest. This lasted for about three weeks, but gave him no discomfort. The treatment was not changed, except that general ultraviolet ray treatment to the whole body was given in place of the local exposure; but this change had already been made on March 4th. On May 1st, the patient was discharged from the hospital for home treatment. At this time his general condition seemed excellent; weight, 124 pounds; skin clear, and the pulmonary condition appeared to be arrested. On February 26th, a blood chemistry examination was made and showed: calcium, 11.3 mgs.; blood nitrogen, 39.9 mgs.; uric acid, 2.4 mgs.; blood sugar, 171 mgs.; red cells, 4,590,000; while cells, 9,800; lymphocytes, 49; hemoglobin, 85 per cent. No blood examination was made before treatment was begun. This case showed an increase of the lymphocytes, a count of 25 being the normal average.

Case VI.—This patient was an ex-service man suffering from pulmonary tuberculosis, moderately advanced. He had been hospitalized for over one year and had received general ultraviolet ray treatment during a greater part of the time, averaging three treatments weekly. His case is now apparently arrested, and he has gained over twenty pounds in weight. On May 15, 1924, he showed a blood calcium of 11.75 mgs. On April 25, 1925, a blood examination showed, calcium, 12 mgs.; hemoglobin, 80 per cent.; red cells, 4,780,000; white cells, 11,800; lymphocytes, 25; coagulation time, one and one half minutes; blood sugar, 68.2; blood nitrogen, 38.4; uric acid, 2.5 mgs. At this time his treatments were changed to twice weekly, and the exposure time reduced to three minutes to each zone. The pigmentation is slight.

Case VII.—This patient was also an ex-service man, suffering from advanced pulmonary tuberculosis, semiambulant. He was referred for treatment of acne vulgaris on the back and upper part of the chest, pustular type, exaggerated in character. The first treatment from the air cooled quartz lamp was given on February 12, 1924; time, two minutes, distance, thirty inches. The exposure of two minutes was for the purpose of obtaining a first degree reaction, or erythema of the skin. Subsequent exposures were increased one minute each until fifteen minute exposures were given. The treatment was then changed to three times weekly, and high frequency vacuum tube treatments were given over the affected area on alternate days. Marked improvement took place, not only in the acne eruption, but in the patient's general condition. On the last day of the year (1924) the ultraviolet ray treatment was changed to include the entire body, except the chest, three times weekly, five minute exposures to each zone, and autocondensation treatments were given on alternate days, 200 milliamperes, twenty minute treatment periods. The patient's condition continues to show improvement, and his pulmonary condition seems to be arrested. His skin has been free from acne eruption for several months. At no time has he shown pigmentation of the skin, although he is a blond of decided type. A blood examination was made on April 14, 1925, and showed the following results: calcium, 10.5 mgs.; blood nitrogen, 34.4 mgs.; uric acid, 2.4 mgs.; blood sugar, 74.6 mgs.; coagulation time, 5 minutes; red cells, 4,440,000; white cells, 21,000; lymphocytes, 28; hemoglobin, 80 per cent. At the time when his treatment was changed to autocondensation the vacuum tube treatment was discontinued.

Case VIII.—This patient, an ex-service man, was suffering from advanced tuberculosis and removal of tuberculous left kidney. He was referred for treatment about three months after the operation. On April 14, 1925, treatment was begun from the air cooled quartz lamp with an initial exposure of one half minute to each of the four zones of the body. Subsequent treatments were increased one half minute daily, until five minute exposures were given to each zone, burner—body distance, thirty inches. After the maximum of five minutes was reached the treatments were changed to three times weekly. Improvement has been constant. The sinus over the operated area is gradually closing, and the discharge is lessening. The patient first came for treatment, from the ward to the physiotherapy department, in a wheel chair. After three weeks he walked to the department for his treatments. He is now receiving open air and heliotherapy treatment. This patient has not suffered material loss of weight. At the time he was referred for ultraviolet ray treatment a blood ex-

amination was made and showed the following: calcium, 11.0 mgs.; blood nitrogen, 32. mgs.; uric acid, 3.9 mgs.; blood sugar, 122 mgs.; red cells, 4,010,000; while cells, 11,000; lymphocytes, 19; coagulation time, 4 minutes; hemoglobin, 85 per cent.

Case IX.—This patient was suffering from tuberculosis, including multiple tuberculous sinuses of the forearms and a tuberculous right mastoid, which latter had been operated upon. He was referred to the physiotherapy department for general ultraviolet ray treatment on November 18, 1924. He came in wheel chair.

At Easter time of this year he went on a five days' pass, which is an indication of his general improvement. All sinuses, except that of the mastoid, have healed, and the mastoid sinus is slowly closing and granulating from the bottom. He has increased about six pounds in weight. On April 25, a blood chemistry examination was made and showed: calcium, 11.4 mgs.; blood nitrogen, 34.5 mgs.; uric acid, 2.5 mgs.; blood sugar, 81.3 mgs.; red cells, 4,840,000; white cells, 11,600; lymphocytes, 25; coagulation time, three minutes; hemoglobin, 85 per cent.

Ultraviolet ray treatments were administered in a manner similar to that employed in Case VIII, except that after he was placed on three treatments a week (general treatment) he was also given three other treatments weekly, locally over the mastoid; duration, three minutes; distance, thirty inches.

Case X.—This patient, an ex-service man, had been hospitalized for some time, suffering from general tuberculosis. He was referred for ultraviolet ray treatment on April 12, 1924. He had a tuberculous sinus in the lower dorsal region. Since treatment with utraviolet rays was instituted improvement has been continuous. Patient now in fairly good condition, sinus nearly healed. Blood examination, April 24, 1925, shows: calcium, 11.0 mgs.; blood nitrogen, 37.5 mgs.; uric acid, 2.7 mgs.; blood sugar, 61.3 mgs.; red cells, 4,628,000; white cells, 8,800; lymphocytes, 15; coagulation time, three minutes; hemoglobin, 85 per cent. Treatment technic similar to that of Cases 8 and 9.

Case XI.—This patient, an ex-service man, was suffering from pulmonary tuberculosis and multiple tuberculous sinuses of the forearms. He was referred for ultraviolet ray treatment on April 14, 1925. The same technic was used as in Cases VIII, IX and X. At the time treatment was begun a blood chemistry examination was made, and showed: calcium, 9.5 mgs.; blood nitrogen, 28.1 mgs.; uric acid, 2.25 mgs.; blood sugar, 147; red cells, 3,390,000; white cells, 13,400; lymphocytes, 24; hemoglobin, 80 per cent.; coagulation time, three minutes. After six weeks' treatment the sinuses are practically all healed.

Case XII.—This was a bed patient, suffering from pulmonary tuberculosis, far advanced. General ultraviolet ray treatment from the air cooled quartz lamp was begun on January 5, 1925. The technic was as previously outlined. This patient also was suffering from tuberculous laryngitis. Improvement began to manifest itself from the first. His weight increased, and his voice showed marked improvement (May 25, 1925). On April 25th a blood chemistry examination was made and showed: calcium, 11.6 mgs.; blood nitrogen, 38.7 mgs.; uric acid, 2.6 mgs.; blood sugar, 94.3 mgs.; red cells, 4,740,000; white cells, 8,200; lymphocytes, 14; hemoglobin, 80 per cent.; coagulation time, 4 minutes.

Case XIII.—This patient, an employee, aged seventy-five years, manifested a severe attack of eczema of both hands, which was most uncomfortable and irritating. Both hands were swollen, dry, cracked, bleeding easily, and extremely itchy. Treatment from the air cooled quartz lamp was instituted, time increased to ten minutes, daily, and preceded by radiant light and heat for ten minutes for softening the crusts.

At first this treatment relieved the condition materially, but failed to effect a cure. Later, the hands became worse, and diathermy to the hands was tried, the hands in a tub of water attached to one pole of the high frequency machine and the other pole attached to a cuff around the arm above the elbow. This method of treatment was instituted as the patient gave a history of having at one time frozen his hands, and the circulation through them seemed rather sluggish. This treatment did not relieve the condition permanently, and the treatment was changed to autocondensation, three times weekly, 800 milliamperes, time, twenty minutes. He was also advised to refrain from work. Improvement was shown almost immediately, and at the present time the hands are normal in appearance, and are giving but little discomfort. Ultraviolet ray therapy was discontinued after a blood chemistry examination was made, on March 14th, which showed: calcium, 12.8 mgs.; blood nitrogen, 36.2 mgs.; uric acid, 3.6; blood sugar, 160 mgs.; red cells, 4,130,000; white cells, 11,000; lymphocytes, 41; coagulation time, four and one half minutes; blood pressure, 150 mm., systolic; 90 mm., diastolic.

Case XIV.—Employee, aged fifty-nine years; calcium, 11 mgs. No treatment.

Case XV.—Employee, aged sixty-five; blood pressure, systolic, 220 mm.; diastolic undetermined; blood calcium, 12.4 mgs. No treatment. Examination was preliminary to employment. The same was also true of Case 14.

CONCLUSION

In connection with these cases, the usual routine hospital treatment was continued, as indicated, during the period of ultraviolet ray exposure. In most instances they had failed to respond satisfactorily until ultraviolet ray therapy was instituted, which renders the results the more striking. Many more cases could be mentioned in which equally favorable results have been obtained; but, as their general characteristics would be somewhat similar, it would be more or less a repetition, and therefore, seems unnecessary.

Miliary Calcification in the Lung.—Charles G. Sutherland (*Medical Clinics of North America*, January, 1925) states that miliary calcification of the lung is a distinct pathological condition. The lesions are characteristic calcified spots, discrete, round, and having a marked absorptive power for the röntgen rays. These spots are widely distributed throughout both lung fields, but are seldom seen above the anterior level of the first rib.

Treatment of Fracture of the Femur

ROYAL WHITMAN, M.D.,
New York

Two papers on the treatment of transcervical fracture of the neck of the femur which have appeared recently (1) seem to merit comment because of the contrasting conclusions which they present. The first is by Professor Koenig, of Würzburg, who subscribes to the opinion of Cooper and Kocher that a complete fracture of this type is practically incapable of repair. This conclusion is, he states, supported by the investigations of Nussbaum on the circulation and the study of specimens by Bonn, Schmol, Hesse and Gurlt, which indicate that necrosis of the head and absorption of the neck are the almost inevitable sequence of the injury, and that even in the possible event of union, arthritic changes in the joint would cause functional disability.

For these reasons Koenig advocates not only removal of the head predestined to necrosis, but with German thoroughness, the neck also in order to forstall its absorption. The projection of the trochanter having been cut away an ovoid extremity is formed, which when placed in the acetabulum assures secure support. He states that with the aim of improving function, he has on the cadaver, though not as yet on a living subject, transplanted the trochanter to the outer side of the shaft, as in the reconstruction operation, of which, apparently, he has never heard (2).

The companion paper is by Professor Anshütz and Dr. Bortwich, of Kiel. They reject primary operation and the conclusions on which it is based because by the abduction treatment a satisfactory result has been attained in four fifths of the cases, and citing similar results reported by others, remark that actual experience is far more valuable than theory. Their material, limited to transcervical fractures, comprises fifty-one cases, personally investigated. Thirty-seven of these were treated by various methods with but little variation in the results which were considered satisfactory in thirty-three per cent. of the cases. The remaining fourteen were treated by the abduction method with satisfactory results in seventy-eight per cent. It is further stated that in only ten of these was the full Whitman technic, including verification of the apposition of the fragments by x ray examination, employed, and that in this group the result was satisfactory in ninety per cent. In their classification a good result is essentially an anatomical and functional cure, satisfactory if the patient can walk half a mile without support, bad if canes or crutches are required in locomotion. From this viewpoint the comparison is even more striking. In the thirty-seven cases treated by conventional methods there were but two good results (5.4 per cent.). In the fourteen cases treated by the abduction method there were eight good results (fifty-seven per cent.), and in the ten cases referred to seven good results (seventy per cent.).

The evidence that has accumulated since the abduction treatment has come into more general use has demonstrated that in the larger proportion of these cases repair is both possible and probable. In many instances a certain loss of substance occurs, but this does not prevent repair if the fragments are fixed in contact for a sufficient time. If, however, nails or screws of bone pegs have been inserted the fragments, in the event of absorption, will be held apart and union prevented by the means intended to assure it.

It may be recalled that Sir Astley Cooper, cited as an authority by Koenig, admitted that the primary cause of nonunion of the intracapsular fracture as of the patella was the impossibility of apposing the fragments, and the mechanical inadequacy of conventional methods to assure the opportunity for repair, is the actual basis of the teaching that this fracture is from the therapeutic viewpoint an exception to all the other injuries of its class. The most notable example of this is the bugbear of impaction which must on no account be disturbed. Originally the diagnosis of impaction was dependent upon interpretation of the physical signs and, usually at present on a misinterpretation of x ray pictures. Its actual influence on the result is well illustrated by the statistics under consideration. In twenty-four of the thirty-seven cases treated by indifferent methods the fracture was classed as impacted and yet there were but two good results.

Deformity after fracture of the neck of the femur, whether the fragments are apposed or not, indicates separation of the fractured surfaces, and contact which in this instance is essential to repair can be restored only by its correction.

If Koenig's statement that intracapsular fractures were incapable of repair were generally accepted there would be, practically speaking, in the future as in the past, no treatment for cases of this class since primary operation would be practicable in but few cases. Furthermore, the larger proportion of fractures at the hip are near the base, yet in this class in which there has been little question of repair, function, in the sense of primary correction of deformity and adequate after care, has been utterly neglected.

The first essential for progress therefore is to discard all the teaching of the past, which, because it is based on inadequate treatment, serves no purpose other than to uphold incompetence and neglect.

Fracture of the neck of the femur should be treated like other fractures with the aim of assuring the opportunity for functional repair and since there is but one method adequate to correct resistent deformity and to fix the fragments securely, a method which is from the life saving standpoint far more conservative than neglect, and when properly applied, far more comfortable than any treatment that enforces dorsal recumbency, the actual question at issue is of the competence of the surgeon to apply it.

The Whitman Reconstruction Operation on the Hip Joint for Ununited Intracapsular Fracture*

With Report of a Case

MORRIS B. COOPERMAN, M.D.,
Philadelphia

The Whitman reconstruction operation for ununited fractures of the neck of the femur has proved beyond doubt a most satisfactory procedure in restoring a painless, stable, weight bearing hip joint. It is especially indicated in those cases where there has been a complete absorption of the femoral neck and rarefaction of the femoral head, which then fills the acetabular cavity practically as a foreign body. The femoral shaft, in these instances, is pulled up by the pelvitrochanteric muscles above the upper acetabular brim and against the side of the pelvis. From a functional viewpoint, this type of fracture is a serious disability. With each step the patient makes, the upper end of the femur either rides up into the fleshy gluteal mass or against the side of the pelvis. Disability and pain are progressive and these patients are naturally doomed to permanent invalidism if this condition remains untreated.

Dr. Royal Whitman, who first described this operation, states that its field of usefulness can be extended to many other conditions of the hip other than fractures, namely, chronic osteoarthritis with considerable limited painful motion or arthritis deformans with ankylosis.

The patient, whose case I am reporting, was in my judgment, a favorable subject for this operation, and the results that have been obtained are extremely gratifying:

Case.—Miss C. D., aged thirty-three, occupation bookkeeper, came to me on May 31, 1924, complaining of pain in the left hip and a marked leftsided limp. She was unable to walk without crutches. Her previous medical history was unimportant. She had always enjoyed good health.

On January 17, 1923, she slipped on the ice, fell, and sustained an injury to the left hip. She was immediately incapacitated and had to be carried to a taxi and then taken home.

She was treated by her family physician, who diagnosed torn ligaments, for a period of six months. At the end of this time, she managed to get around the house on a pair of crutches but could bear no weight on the left side. If she attempted to do so, she felt insecure and had pain. One year after the accident, an x ray was taken in a hospital, where she was told that a dislocation of the hip existed. The only advice given was to have a lift put into her left shoe to compensate for the shortening. During this period, she tried a chiropractor, who administered spinal adjustments. Obviously, the condition did not improve and the girl was becoming resigned to permanent invalidism. She had also been treated by two or three other physicians but without any definite advice.

Examination showed a marked left sided limp, a left postural scoliosis with rotation of the lumbar segment. The pelvis was tilted downward and forward toward the left side. The measurement of the lower extremities showed a shortening of the left limb of three inches. The trochanter was two and three quarter inches above Helaton's line and there was a vertical movement of the femur through a distance of two inches.

A tentative diagnosis of ununited fracture of the neck of the left femur was made.

This was confirmed by a röntgenographic study made by Dr. Mulford K. Fisher, whose report is as follows: Old intertrochanteric fracture of the neck of the femur, with an upward displacement of the shaft on the ilium, a distance of three and one half inches. No evidence of bony union. The head of the femur, which has undergone considerable absorption, is in the acetabular cavity.

The patient was admitted to the Polyclinic Hospital on June 17, 1924. The procedure which I had in mind before performing the operation, was to bring the upper end of the shaft of the femur in better relation to the acetabular cavity, because the femoral shaft was above the normal position, held so by contracture of the iliotrochanteric muscles. To attain this, I applied fifteen pounds weight to the left thigh and maintained it for a week.

A röntgenograph made at this time by Dr. George E. Pfahler showed the following: There is an ununited fracture of the neck of the femur with its complete absorption. The head is rarefied, lies free and fills the acetabular cavity. There is an upward displacement of the shaft of three and one half inches.

On June 29, 1924, the reconstruction operation was performed, following the technic of Dr. Royal Whitman, the steps of which were as follows: An incision was made in the shape of a half U beginning one inch behind the anterior superior spine extending downward and backward, crossing the femur about three inches below the apex of the trochanter. This exposed the interval between the tensor fascia femoris through which the capsule was opened and the head of the femur removed. The trochanter was then cut through at its base and turned upward. The upper extremity of the bone was then rounded off and made smooth. A thin slice of cortical bone was removed from the outer surface of the shaft at its upper end and the trochanter with all of the attached muscles was sutured to the shaft by kangaroo tendon. The upper end of the shaft was then inserted into the acetabular cavity and to maintain its position, the thigh was placed in a position of 50° of abduction. The capsule of the hip joint was closed with an uninterrupted row of sutures and the wound was closed without drainage.

*Read before the Southeast Branch of the County Medical Society, May 7, 1925.

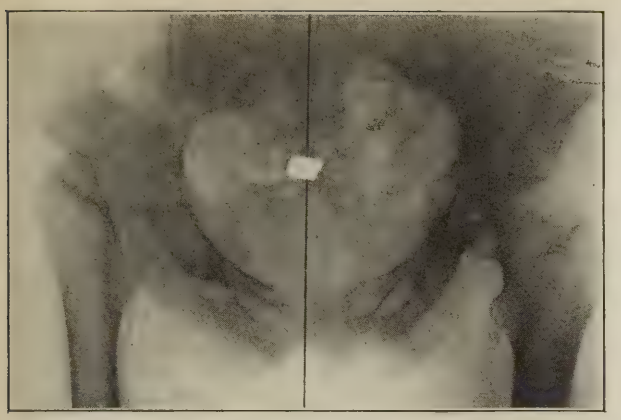

FIG. 1.—Shows the left hip before operation. Note complete absorption of the femoral neck, the upper displacement of the shaft of the femur and the partially absorbed head in the acetabular cavity.

A plaster of Paris cast was then applied, with the hip in the position indicated above, the plaster reaching from the thorax to the toes, the foot pointing straight upward and at right angles to the leg. The duration of the operation was an hour and fifteen minutes, including the application of the cast. The patient bore the operation extremely well and there was no postoperative shock.

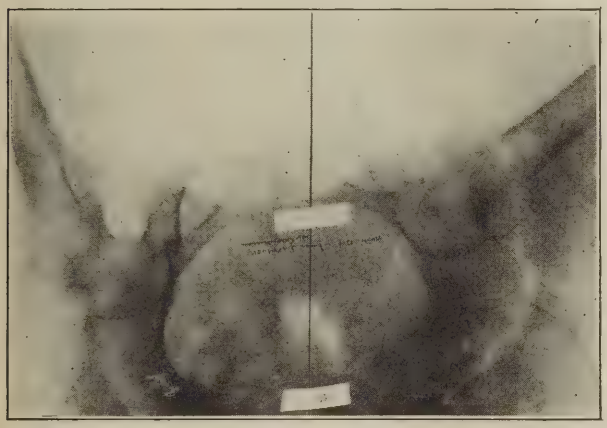

FIG. 2.—Shows the newly formed neck in the acetabular cavity, the thigh in 35° of abduction, the trochanter anchored to the shaft.

For the first three weeks after operation, the pulse, respiration and temperature were normal. At the end of this time, there was a slight rise in temperature and the patient complained of a burning, throbbing pain at the site of the operation.

FIG. 3.—Shows the femoral neck in position.

To investigate this, I made a window in the cast and found that a small, stitch abscess had developed in the upper pole of the wound. This was dressed daily and healed in a week.

The cast was removed at the end of six weeks. The limb was then brought down into 35° of abduction and another cast applied, also from the nipple to the toes. An x ray taken at this time showed the newly formed neck in the socket.

On October 2nd, this cast was removed, and the examination revealed the following: The newly formed neck was apparently in the acetabular cavity. There was no upward movement. The limb was in 35° of abduction with the trunk, and it could be adducted 25°; there was 25° of flexion, extension 0; internal and external rotation 90°; measurement from the anterior superior spine to the internal malleolus showed a shortening of one and one half inches; the knee had a range of motion of 45°.

An x ray taken two days later showed the newly formed femoral neck in the acetabular cavity, and the trochanter anchored in position.

A shoe was made for the patient with a lift of one and one half inches to compensate for the shortening and she was encouraged to bear weight upon the affected side.

For a period of three months she received a course of daily massage and manipulation to the knee and hip.

On January 15, 1925, an examination showed the following condition: Flexion 45°, extension 10°, abduction 40°, adduction 15°, internal and external rotation 90°. The knee flexes to 90°. There was a right dorsal left lumbar scoliosis. The patient was walking without assistance, with practically no discomfort. She was still not able to sit comfortably.

On May 5, 1925, an examination showed the following: The hip could now be flexed to 70°, the knee through an arc of 160°. She could walk some distance without any pain whatever and could sit without discomfort. The only complaint which she had at the time was that she could not stoop to lace her shoe. She was delighted with the results. There was, of course, a perceptible limp.

An x ray examination made May 2nd showed the newly constructed neck of the femur lying in the socket and the trochanter appears solidly attached to the shaft.

According to Dr. Whitman, the operation described can be performed without regard to age limit. This operation would be a great boon to many aged persons. When they sustain such an injury, it is usually considered hopeless and they are left to spend their days disabled and in pain.

It would be certainly a worth while procedure in pathological dislocations following disease in which the articulation has been in part destroyed, assuming, of course, that there is a fairly good acetabular cavity.

In conclusion, I might state that this operation should be given more universal consideration.

2017 PINE STREET.

Hanot's Cirrhosis

KENNETH MURRAY, M.D.
Battle Creek, Mich.

Cases of Hanot's cirrhosis are probably sufficiently rare to warrant the reporting of a single case, especially when it is quite typical in its clinical aspects.

Case I.—H. C. Z., aged twenty-seven, applied for treatment on account of jaundice which had lasted one year, loss of twenty pounds weight in one year, and general malaise for three or four years. The family history showed that the father died at forty-seven from cancer of the stomach. The remainder of the history was negative. He had had the ordinary diseases of childhood of a milder variety, and influenza in October, 1923; no venereal disease. He was a moderate smoker; did not use alcohol.

Concerning the present illness, the patient did not think he had been absolutely well since 1920. At that time he spent a year in the Argentine Republic. During his stay he recalled having had several attacks of moderately severe diarrhea, each one lasting three to four days at a time, and associated with colicky abdominal pain. He passed no blood or mucus in the stools during these attacks, which, by the way, were not sufficiently severe to cause him to discontinue work. There was no noticeable loss of weight. He returned from the Argentine in 1921 feeling fairly well. Not long after his return home he began to notice some indigestion characterized by bloating, belching, and sour stomach, and a slight loss of weight. Early in 1923 he suffered from slight cramp-like pains referred to the epigastrium, unaccompanied by nausea or vomiting. With this indigestion he had some fairly severe attacks of diarrhea, associated with the passage of blood and mucus in the stools. Frequently he had involuntary passages. In the spring of 1923 he went to the Adirondacks where he picked up considerably in health. While there, however, he noticed considerable itching and burning about the feet and legs. In a month's time he noticed a definite jaundice which had gradually deepened since. In October he had influenza. At this time some enlargement of the liver was noted and since then he had suffered considerably from itching. He had had no nausea and no vomiting but a gnawing sensation in the epigastrium. There had been no return of the diarrhea, in fact his bowels were somewhat constipated. Lately his stools had been rather light in color, at times almost a clay color.

The symptoms noted were a slight cough; no expectoration; no circulatory symptoms; nocturia—from one to five times a night; no hesitancy, dribbling, dysuria or hematuria. His sleep was disturbed on account of frequent urination and itching.

The physical examination showed that the patient's development and nutrition were distinctly below par. The skin showed a fairly deep jaundice and the conjunctivæ had a marked icteric tinge. There was evidence of irritation of the skin, probably from scratching. The tongue was moist and clean, the teeth were in good condition, the pharynx clear except for the distinct yellowish tinge. There were some palpable cervical glands, the thyroid was not enlarged.

Nothing abnormal was noted in the respiratory system. The circulatory system was negative except for a slight bulging over the precordium; pulse 72; blood pressure 100/50. The abdomen moved freely on respiration and appeared to be somewhat distended. The umbilicus was pushed up as though from intraabdominal pressure and there was general tenderness over the upper abdomen, but no rigidity. The liver was palpable on full inspiration for about two inches below the costal margin. Its edge was smooth and regular, quite firm, slightly tender. The spleen was also enlarged for about one inch below the costal margin; the splenic notch was readily palpated. There was no evidence of ascites. The abdomen was otherwise negative, no hemorrhoids. An examination of the nervous system showed the pupils equal, regular, and reacting to light and accommodation; knee jerk present and active. The remainder of the neurological examination was also negative.

Laboratory investigation: Urine varied from 700 to 1600 c. c. in the twenty-four hours; specific gravity 1.011 to 1.018; no sugar, no albumin in any specimen; bile pigments present in all specimens; no pus or casts noted. Blood count on admission, red cells 3,760,000, white cells 9,600, hemoglobin 73 per cent. On discharge, seven weeks later, the red cells were 3,820,000, white cells 9,300, hemoglobin 87 per cent. Differential blood count 66 polymorphonuclears, 23 small lymphocytes, 3 large lymphocytes, 2 eosinophiles, red cells varying slightly in size; blood Wassermann was negative; nonprotein nitrogen 26.2 mgms. to 100 c. c. of blood, sugar 100 mgms., uric acid 3.1 mgms.

The examination of the feces gave no reaction for blood or mucus. Bile salts were found in all specimens. The examination of several warm stool specimens revealed no parasites. Gastric test showed mucus in several specimens; no bile. Two specimens showed lactic acid. The fractional gastric curve for the combined acid ranged from ten in the residuum gradually up to thirty-four at the two and one half hour observation. There was no free hydrochloric acid noted except in the final specimen where it was twelve.

The barium meal was essentially negative except for the enlargement of the liver and spleen, and some slight iliac delay. Liver function test: Hemoclastic, 13,800, 13,800, 16,200, 17,700. Biliary drainage showed the ordinary light amber color in the A and C specimens, while the B bile was a darker amber color. The gross examination showed the bile to be almost crystal clear. Microscopic examination revealed no evidence of pathology. Ferments apparently normal. Staphylococcus was removed from the A and C bile, while the B bile was sterile. This examination was essentially negative.

The patient was treated symptomatically, with tonic baths, general blood building diet, hot and cold applications over the liver, light massage, sun baths and various drugs to combat some slight diarrhea which was present at first. His weight remained

stationary throughout the treatment; he ran a slight temperature of 99° to 101° almost every day, for which no cause could be found beyond the cirrhosis. The hemoglobin improved slightly; the jaundice became less conspicuous, probably because of the brown pigmentation of the skin resulting from sun baths, as the conjunctival icterus remained unchanged. In our opinion the patient improved slightly during treatment.

The original hypertrophic biliary cirrhosis was first described, not by Hanot as many believe, but by Requin in 1846, to whom Hanot himself gives the credit of being the first to draw attention to this peculiar form of cirrhosis. Previous to that time knowledge of cirrhosis had been contributed by Laennec who stated, "A liver which contains cirrhosis loses of its volume instead of increasing in the same proportion." Hypertrophy with cirrhosis was admitted by a few who stated that it was strictly confined to the early stages of common or Laennec's cirrhosis. Todd, of England, in 1857, stated that it was a separate and distinct malady having nothing to do with cirrhosis. Requin, however, published his case describing a liver of 3,900 grams with marked evidence of cirrhosis both macroscopically and microscopically. Gubler in 1853 reported several such cases, and shortly after Lacoze, Genouville, Charcot, Luys, and others, contributed to the literature on the subject. Before that time the condition had been somewhat obscure and was looked upon as a special malady of the liver having nothing to do with cirrhosis. The first detailed description which included a number of cases with necropsy reports was given by Hanot in 1871, in which thesis he draws attention to the clinical difference between the alcoholic cirrhosis (synonyms, periportal cirrhosis, multilobular cirrhosis, Laennec's cirrhosis, gin drinker's liver) and the hypertrophic or unilobular variety. Since that time this rather uncommon condition has been associated with his name.

The etiology of this condition is still somewhat obscure. The finer biliary radicles seem to be the most affected, and on this account some have thought it to be an ascending affection from the duodenum, but the absence of any especial change in the pancreas seems to be against this theory, unless of course the infecting bacteria encounter less resistance in the bile than in the strong digestive juices of the pancreas. It is possible the infection is blood borne but the fact that the portal areas apparently escape would not lead us to believe this the case. We are still in the position of Hanot when he wrote:

"Quant à l'origine même de la maladie tout ou presque tout est hypothèse pour l'instant. S'agit-il d'une infection d'origine intestinale ou d'origine biliare? Peut être est-cedans cette voie encore inexplorée qu'il faut chercher la solution du problem."

The condition is most common in young adult males under thirty-five years. Cases have been reported in infants but these are rare. Heredity is probably not a factor. Alcohol, which plays such an important role in the etiology of the periportal variety is not a factor in this condition. Laennec's cirrhosis occurs in middle life or later, while Hanot's cirrhosis occurs in youth and middle age. Hanot's cirrhosis is characterized by enlargement of the liver and spleen, jaundice and irregular fever, which symptoms may persist for years. The stools are usually colored. The urine is usually dark from bile pigments.

Symptoms of the condition come on gradually, ushered in usually by some mild gastrointestinal disturbance followed by a slight painless jaundice, which gradually increases in intensity. There is usually an irregular fever from 99° to 101°. A moderate loss of weight sometimes follows but the patient may preserve his nutrition to the last. The itching from the jaundice is often intense and presents an aspect which is difficult to combat. Diarrhea alternating with constipation is frequently seen.

A diagnosis of Hanot's cirrhosis should only be arrived at after a careful consideration of other possibilities. This is quite obvious as many conditions resembling Hanot's cirrhosis are curable, while Hanot's cirrhosis invariably ends fatally. This calls for extensive investigation both clinically and employing laboratory methods. Patients must be observed over a considerable period of time, preferably in an institution. The other conditions which must be thought of are:

LAENNEC'S CIRRHOSIS

The term atrophic, when applied to this condition, is a misnomer, as frequently the liver is several times normal size. Cases have been reported where this organ weighs 6,000 grams. The condition usually occurs in males in middle life or later. There is usually a history of alcoholism, although this factor is not absolutely essential, because it is generally conceded that something else besides alcohol damages the liver. This unknown factor is probably an infection. In most cases of periportal cirrhosis the liver is not enlarged. The spleen may be slightly enlarged; generally it is of normal size. Typical late cases show evidence of ascites. Some cases of Laennec's cirrhosis have a slight icteric tint, but rarely reach the deep jaundice of Hanot's cirrhosis. Chronic tubular nephritis may go on slowly to form a picture of chronic interstitial nephritis, so also a liver fibrosis which is primarily interlobular may extend until it becomes intralobular and affect the bile ducts, ultimately producing jaundice. Unless there are complicating conditions such as tuberculosis, which is frequent, no rise of temperature is found.

SYPHILIS

The introduction of the Wassermann reaction and its general employment in obscure cases has revealed that syphilis may cause some confusion if a diagnosis is attempted by clinical means alone. Hanot cites the case of a woman with enlarged liver and spleen, slight, irregular fever, with jaundice, where the diagnosis was Hanot's cirrhosis, but the case, coming to autopsy, showed unmistakable evidence of syphilis.

COMMON DUCT OBSTRUCTION WITH STONE

The difficulty should not be great here. A history of rather sudden onset with pain is suggestive. The jaundice seldom persists for any length of time without biliary colic. There may be some infection or cholangitis, causing a rise of temperature and even some slight enlargement of the spleen, but this latter organ seldom obtains the size one sees in Hanot's cirrhosis. Also x ray of the gastrointestinal tract will show a stone in forty per cent. of cases.

Common duct obstruction from pancreatic neoplasm may cause confusion. It is to be remembered that ten to twenty-five per cent. of these cases show no jaundice when they come to autopsy. These, of course, will not be confused with Hanot's cirrhosis as the jaundice in this condition is striking. The temperature is generally normal or subnormal, unless complications are present. The wasting is rapid and the jaundice increases with greater rapidity. Glycosuria may be present. Fatty stools are common owing to obstruction of the ducts. The presence of an enlarged gallbladder is evidence in favor of this condition.

CATARRHAL JAUNDICE

The history is helpful in cases of catarrhal jaundice, including those of poisons such as salvarsan, benzol, and similar drugs. In the latter conditions there is usually atrophy of the liver instead of hypertrophy. There is no enlargement of the spleen. The jaundice of this type will subside in a few weeks.

MALARIA

This condition is quite uncommon in temperate zones, especially that variety where the symptoms are marked and jaundice and hypertrophy of the liver and spleen are present. Occasionally one sees malaria with digestive disturbances, loss of weight and strength, yellow color of the skin in the late stages, hypertrophy of liver and spleen, diarrhea and albuminuria. A careful search for parasites in the blood will give important information. Some maintain that these parasites are liable to be found in the peripheral blood stream following perspiration from a sweat bath. The temperature chart may show a quartan or tertian type of the disease. The presence of chills is not usual with Hanot's cirrhosis. Finally in doubtful cases no harm can result from a therapeutic test of quinine.

BANTI'S DISEASE

There is a strong tendency to diagnose cases of anemia associated with splenomegaly as Banti's disease, without a thorough searching investigation. The early stages of this condition should present no confusion with Hanot's cirrhosis. This is fortunate, as splenectomy will cure the whole malady in early cases, providing it does not kill the patient through uncontrollable hemorrhage at the operation. In later stages of Banti's disease, jaundice with cirrhosis of the liver may be present. Usually the history of repeated hematemesis is significant. Ascites is the rule in late Banti's disease.

CARCINOMA OF LIVER AND BILE DUCTS OR GALLBLADDER

These are probably more liable to be confused with cancer of the pancreas. Carcinoma of the liver, either primary or secondary, may occur after forty years, but secondary cancer of the liver with primary cancer in the colon may occur in early youth. Zuppinger has reported a case in a girl two years of age, and another in a boy of thirteen years (Ruczyuski). Jaundice is frequently present both from pressure on the hepatic ducts from extension within the liver and also from enlarged lymph glands at the portal fissure. Fever is not uncommon. The liver may or may not be painless; ascites is the general rule. The x ray may reveal primary cancer in the gastrointestinal tract. A primary cancer in the liver is rather uncommon. The spleen is not generally enlarged unless, of course, it contains extension of the neoplasm. The liver in this condition is quite nodular, while in Hanot's cirrhosis it is only slightly irregular or even quite smooth.

FAMILIAL HEMOLYTIC JAUNDICE

This condition is either congenital or occurs in early childhood. It is characterized by an enlarged spleen, a history of jaundice in the parent, and increased fragility of the red blood cells in hypotonic salt solution. These cases are acholuric; there is no itching with the icterus; in fact, as Moynihan has pointed out, these patients are more jaundiced than ill. The enlargement of the liver is not so marked. It should be remembered that gallstones occur in some sixty per cent. of cases.

In connection with the differential diagnosis of jaundice with enlarged liver and spleen, mention should be made of the newer liver function tests including the tests for hemolytic or obstructive jaundice introduced by van den Bergh of Utrecht. I have not had enough experience with these to warrant an opinion. No doubt they will prove useful in their place. In a multifunctioning organ such as the liver, it should, of course, be kept in mind that these tests will show one single function only; whereas the liver may be deficient along one line, it may be highly efficient in others.

Normally, the liver averages some 1,600 grams in weight. In Hanot's cirrhosis the liver is definitely enlarged to 2,500 or 3,800 grams. The surface is finely granular and of a greenish tint. On section, it is firm and the cirrhotic lobules present the appearance of granite. Microscopically there is a delicate fibrosis of the individual lobules. The individual lobules show fine fibrosis while delicate strands of connective tissue isolate small groups of liver cells. The portal system appears to be free. Hanot's original cases were mostly those seen in an early stage in patients who had died from an intercurrent disease. This microscopical picture is contrasted in Laennec's cirrhosis by the proliferation of connective tissue enclosing several lobules (multilobular cirrhosis). In advanced cases the connective tissue is occasionally seen to infiltrate the liver cords, but this latter intralobular invasion is rare, while in Hanot's cirrhosis it is typical. The spleen, the normal weight of which ranges around 200 grams, in Hanot's cirrhosis will be found enlarged from 500 to 1,200 grams; indeed some spleens are even larger than the liver. Microscopically it is characterized by endothelial proliferation. The alimentary tract is clear.

TREATMENT OF HANOT'S CIRRHOSIS

There is no specific treatment. If, after biliary drainage, organisms can be cultured from the common duct or C bile, vaccines can be tried, but it would seem that enough antigen is already present to furnish stimulation for antibody production. Modified rest is indicated depending on the patient's physical condition. In our case the patient was kept in the open air gymnasium with the whole of the body exposed to the sun for several hours each day. This seemed to increase his strength to a certain degree. The diet should be watched carefully as these patients have an irritable gastrointestinal tract which is characterized at times by alternate constipation and diarrhea. We were unable to notice any appreciable

change in his condition which we could attribute to biliary drainages, a number of which were tried. Improvement as the result of this therapy could scarcely be expected as the fibrosis and scarring had probably already progressed to an irreparable degree.

The jaundice is a stubborn and irritating condition seemingly more noticeable when the patient becomes warm and perspires. Sponging with two per cent. phenol solution is helpful, or a dusting powder of equal parts of sodium salicylate and starch can be tried. Calcium chloride intravenously in doses of five c. c. of a ten per cent. solution, often so advantageous in the itching of many jaundiced conditions, we found quite ineffectual.

PROGNOSIS

The prognosis for cure is bad. These patients live in a fair degree of health from fifteen months to nine years. The end usually comes accompanied by increasing cachexia, deepening jaundice, stupor, convulsions and more rarely hemorrhages.

CONCLUSIONS

1. A case presenting the clinical symptoms of Hanot's cirrhosis is reported.

2. It is of decided importance to investigate thoroughly cases of splenomegaly with jaundice and enlargement of the liver, as cases of this type are at times confusing.

3. An early diagnosis in cases of this type is highly essential and a diagnosis of Hanot's cirrhosis should be considered only after thorough investigation.

4. As these patients live for some time, it is necessary that they be made as comfortable as possible.

Control of Morbidity and Mortality of Diphtheria

DWIGHT M. LEWIS, M.D.
New Haven, Conn.

Control of morbidity as well as of mortality for diphtheria, unequalled in typhoid fever, is possible for two reasons. First, nasal carriers of diphtheria are pathologically evident to the eye and confirmed by bacteriological examination; secondly, frequency of the common respiratory diseases, measles in the main, is causative of nasal diphtheria carriers.

In a recent article in this journal (1) biological evidence was given as to the production of virulence in the diphtheria carrier. At the 1924 annual meeting of the American Public Health Association I presented statistical evidence showing that the variations of rates for morbidity and mortality during a period of fourteen years in New Haven confirmed the field evidence of the two main factors causative of these variations, one factor, the nasal carrier, and the second factor that of other respiratory disease frequency, measles in the main (2).

Yet more recent statistics are now available to demonstrate more clearly actual control of morbidity and mortality of diphtheria. Properly to apply and appreciate the statistics, a review of conditions may be given. During and following a measles epidemic in 1914, in New Haven, the apparent interrelation between nasal diphtheria carriers, measles and the ensuing increase in cases of diphtheria was first observed. Having but one assistant, an inspector, search for, and isolation of nasal carriers was at the time possible in but one district. Beginning in the district where measles first started, an appreciable diminution of both cases and deaths in diphtheria for the following year occurred to the exclusion of all other city districts where increases followed. Following an epidemic of measles in 1917, based on the results of 1915, two nurses were employed for two months. In that time they made a nasal inspection of approximately the entire school population, a total of 35,000. Definite reductions in every district of the city in morbidity and mortality for 1918 for diphtheria could be shown. With a change in administration for the next three years, these procedures were held in abeyance.

Epidemic measles in 1920 was followed by an increase in morbidity and mortality for diphtheria for every city district. Again taking up the work at the close of 1921, the personnel of the bureau now comprised two nurses in addition to the inspector. Epidemic measles in 1922 again furnished the opportunity, together with the fact that one city district had been taken over in mid 1920 for a three year demonstration health centre. Under a separate medical direction, our procedures were not in force in that mentioned district. In mid 1923 this district health centre was closed and the district again merged with the city department. With an additional nurse an opportunity offered of systematically combing this district for nasal carriers. An expected probable measles epidemic for the year 1924 showed only as a high frequency practically limited to this district and appearing late in the spring. As a result of the combination, over half of the year's diphtheria carriers for the total city were found in this district, the majority of the carriers being found during and after the measles frequence among those affected, or their contracts.

TABLE I.

MORBIDITY AND MORTALITY RATES FOR DIPHTHERIA FOR DISTRICT A, DISTRICT HEALTH CENTRE AND CITY EXCLUSIVE OF HEALTH CENTER.

	1922	1923	1924
District A			
Morbidity rate	183	60	42
Mortality rate	12.5	2.5	0
District health centre			
Morbidity rate	125	100	60
Mortality rate	11	14	3.2
City, exclusive health centre			
Morbidity rate	100	55	35
Mortality rate	4.9	2.8	1.4

Our premises are, then, that diphtheria morbidity increases during and following epidemic measles, and that diphtheria mortality increases during the

last half of the year where measles is epidemic during the first half, and extends into the first half of the following year. Accepting the fact we have previously shown, that a city district, later called district A, had yearly been comparable with the health center district by reason of higher case and death rates from diphtheria, with a half greater population and more cosmopolitan in composition. Table I bears out our premises.

The accompanying chart shows the morbidity and mortality rates for the four cities of the state with populations in excess of 100,000 and for our neighboring cosmopolitan city. The rates for the first nine years are taken from the annual reports of the United States Public Health Service, mortality rates for New York city excepted. In the latter instance figures from the United States Census Bureau Report 1910-1920 are used in that the rates show wider variations. The figures for the Census Bureau are inclusive of nonresidents, a fact of excess rates for Hartford and New Haven, but of no moment for New York city.

It will be seen that the curves for both morbidity and mortality for New Haven are in accord with the rather uniform, wide variations of the other four cities of the state during the years 1919-1921 and to a slight extent for 1917-1918. Alone of any one of the sets of curves, that for New Haven departs from all others for the year 1922, an epidemic measles year is the first instance of a lowered morbidity rate and for 1922 and 1923 for lowered mortality rates. Yet even in this city the general rule did hold good for increased mortality rate, 1923 for one district only, the health centre as shown in Table I. No less important may be the upward trend for New York city, in 1924. In 1923 two of the five boroughs showed new low levels, Manhattan with one of 8 and the Bronx with one of 4.3. For 1924 following epidemic measles morbidity and mortality from diphtheria were increased for the various boroughs, the widest variation being the Bronx with a half greater morbidity, 133, and a mortality rate of 10.8.

One may readily understand why increased morbidity and mortality for diphtheria may follow epidemic measles when dependent on the tide of nasal diphtheria carriers produced. Why, as is very generally found, the increased mortality should extend into the following year, is one of the important phenomena connected with diphtheria. Constituting as it does an increased case mortality rate, investigations are concerned with the possibility of severer types of disease, of an excess of unreported cases or with the lateness, insufficiency or impotency of the antitoxin. Our experiences of 1916-1917 were that "visibly sore noses" were frequently a pure culture of streptococci, that immediate contacts of such nasal carriers were clinical cases of diphtheria although bacteriologically streptococcal, and that one of the periods of their frequency was during measles epidemics. With the cessation of the measles frequence, there followed streptococcal sore throats, both primary and complicating true cases of diphtheria. It was not an unusual occurrence to have one convalescent from true diphtheria die from a complicating streptococcus. With susceptible material on the wane, the streptococcal infections came to the fore, and with more age groups susceptible than with diphtheria, the increased mortality rates included deaths from diphtheria, where bacteriologically and epidemiologically numerous immediately preceding contact illness of families and neighborhoods bespoke the unproved case as not a true case of diphtheria. Our experience was that clinical laryngeal diphtheria

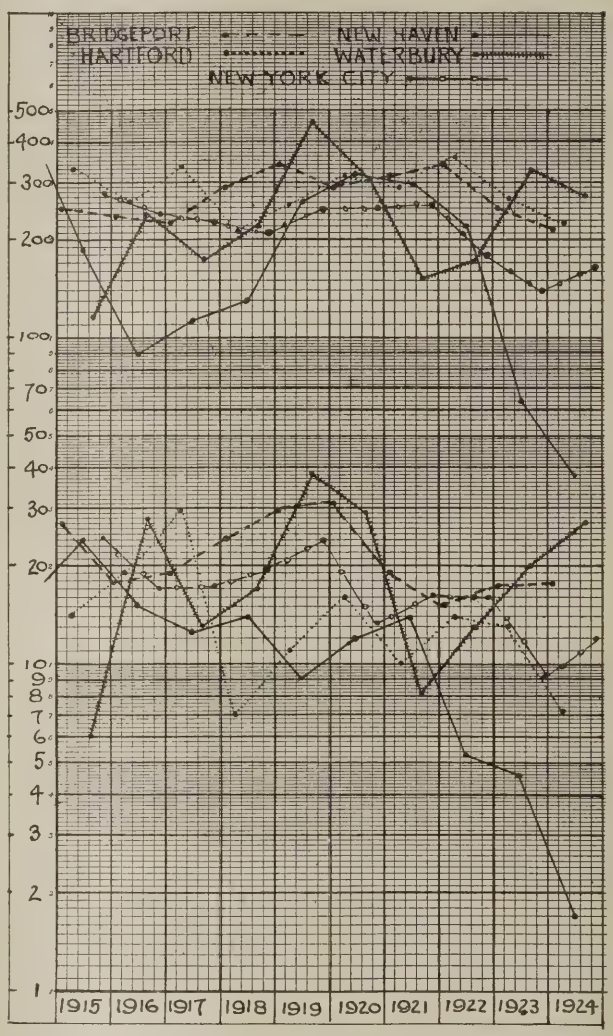

Chart showing morbidity (upper) and mortality (lower) rates of diphtheria in 100,000 of population, in Bridgeport, New Haven, Hartford, and Waterbury, Conn., and New York City.

of early childhood during the early year following epidemic measles of the previous year was of the first order in this ensuing increased diphtheria mortality. To have as was recently the experience of more than one city, an unusual epidemic of diphtheria with unusually high mortality where it was the experience that deaths occurred irrespective of early and sufficiency of antitoxin, sidetracked the issue when the only explanation was that the experience bore some relation to the influenza epidemic preceding.

With our previous experience of former years we have during and following the measles epidemic of 1922, isolated and held for cure every "visibly sore nose." With equal assurance we pass by the ordinary common head cold. Ten years ago an afternoon's drive through streets where children congregated never failed to net a number of nasal carriers. At the present time five individuals as

keenly search, but with infrequent findings. The value of frequencies of respiratory disturbances may be shown in the following instances. The first three months of 1923 were characterized by an unsual amount of school absenteeism for minor illnesses. Out of the several thousand of children out of school for more than three days who passed before me in the office for a school permit, I found by nasal inspection fifty diphtheria carriers. For the similar period, 1924, unmarked by notable respiratory disturbances, I found but one nasal carrier, while for the same period for 1925, a period as notable for school absenteeism as in 1923, I have found but a single nasal carrier.

CONCLUSION

There are definite opportunities of controlling hitherto uncontrolled morbidity for diphtheria as well as controlling excesses of mortality. Measures to be effective must have consideration for other intercurrent respiratory diseases which not only complicate but stimulate the disease diphtheria. The main factor in the spread of diphtheria is the nasal carrier of diphtheria. Excesses of morbidity are a measure of the tides of nasal carriers produced by intercurrent respiratory diseases, measles in the main. Excesses of mortality have a further factor. Nasal carriers of other infections simulating as well as complicating diphtheria must also be controlled. Effective administrative measures are no less responsible health department procedures, as was formerly theorized; they are merely a rearrangement of eyes and nose and substituting the common diseases of man for the older concept of environment.

Pituitary Type of Headache

HENRY R. HARROWER, M.D.,
Glendale, California

About the year 1913 I had occasion to analyze a number of cases of severe headache associated with menstrual irregularities, and came to the conclusion that the suggestion which I was then studying—the suggestion of Professor Paul Dalché of Paris that the thyroid aspect of menstrual irregularities was extremely important and that ovarian therapy really should be broadened by the addition of a suitable amount of thyroid—could be made still more effective by considering the possible pituitary aspects of this evidently pluriglandular disorder.

It is clear that the pituitary gland, almost equally with the thyroid, is definitely concerned in the initiation as well as the maintenance of the function of the sex glands and perhaps, more particularly, of the female sex glands.

In considering several of my own cases as well as a number in the hands of various colleagues, it was evident that the pressure type of headache, not unusual in cases of more or less serious menstrual irregularity, might be considered to have a fundamental pituitary origin. In view of this and because there was other evidence of a pituitary defect in certain of these cases, pituitary substance was added to the treatment, thus replacing ovarian therapy first with ovary plus thyroid, and later with ovary plus thyroid plus pituitary. The remarkable broadening of this particular form of organotherapy by the addition of a small dose of total pituitary substance was most noteworthy in this special type of cases, that is, those in whom the menstrual irregularity was accompanied by a serious headache.

While it is difficult to study a condition of this kind from the point of view of accurate laboratory physiology and comparatively easy to study it from the more empirical and less appreciated clinical method, we had to presume that the added demands upon the pituitary during the period of ovarian difficulty, caused an increased blood supply to this gland and consequent temporary hypertrophy, for hyperemia is consonant with hypertrophy, especially when the organ happens to be enclosed in a closely fitted sella turcica.

It was clinical results which so often followed this form of pituitary therapy, and particularly the results in the cases that had only been modified partially by ovarian therapy or ovarian thyroid therapy alone, that caused the conclusion that there was indeed a definite functional pituitary type of headache.

Later on, we obtained more information on the subject and our appreciation of the method was made clear by papers on the subject by several writers.

Quite recently a Chicago internist, Joseph L. Miller (1), prepared a paper on pituitary therapy as a part of a series of articles on glandular therapy, published toward the close of 1924. In the course of this article, Dr. Miller indicated that he was not well posted on the clinical use of pituitary substance in cases of this kind, and had not read the literature very thoroughly, since he made this statement: "There has developed recently considerable literature on the value of pituitary substance by mouth in the treatment of pituitary headache. A review of the literature fails to reveal a headache that justifies this name, except in cases in which a tumor is present."

This clearly indicates that Miller does not believe in pituitary headache except when obviously due to a pituitary tumor. Such a mistake should not be permitted to go unchallenged, and, therefore, I submit herewith a number of excerpts and supplement them with some clinical experience which I do not believe can be gainsaid.

The two most important papers in the American

medical literature are those by Pardee of the Neurological Institute of New York and Engelbach and Tierney of St. Louis. The former writer (2) makes the following statement: "A disproportion between the pituitary body and the sella produces pressure on the sensory nerves to the dura; and by its encroachment on the cavernous sinuses it may cause interference with the cerebral circulation, the whole setting up the train of pituitary symptoms, including headache."

Pardee proceeds to give the clinical impression that such a headache produces. He says, "The headache is situated deep in the forehead behind the eyes. Deep pressure on the temples may elicit some tenderness. This headache is very persistent, usually lasting from half an hour to forty-eight hours, and it may be continuous, frequently coming on in the female at the time of the menses."

Further on, in the same paper, Pardee makes a statement which is quite different from that made by Miller; he says, "The administration of whole pituitary is specific . . . . . continuous medication with pituitary will result within a few days in a decrease in the intensity of the headaches; there will be a longer period between their return," etc.

Another writer, J. Allison Hodges (3), of Richmond, Va., seems to be more in agreement with Miller when he says: "Pituitary headaches are not the result of functional disturbances, but are due to anatomical abnormalities, which, in part, interfere with the proper functioning of the pituitary gland, this type of headache being due to an altered secretion of the pituitary which causes swelling and consequent permanent enlargement of the gland." Hodges proceeds to speculate as to whether this enlargement is caused by some compensatory demands upon the gland, and then remarks, "The fact remains that the pituitary gland in many cases does enlarge, and because of its anatomical position and consequent constriction in a bony enclosure . . . . . is not allowed to expand; consequently there must arise pressure symptoms and resultant localized pain." Still further along in the same article is this statement: "Pituitary headaches in properly selected patients are uniformly responsive to glandular therapy in proper doses."

I cannot quite agree with Hodges that these headaches are due to definite anatomical abnormality. While it is perfectly true that hyperemia brings about an anatomical change in an organ, this is not comparable to an abnormality such as one expects in tumor. Its functional character in a great many of these cases permits its reduction and disappearance following proper treatment or the removal of the underlying cause, hence it does not seem fair to consider these headaches as due actually to an organic or anatomical change, at least, not a permanent one.

John A. Glassburg (4) of New York considers the pituitary headache in rhinological practice, and says, "I wish to emphasize the fact that there is a definite distinct type of headache which is met quite often in rhinological practice; that this headache is due to a disturbance of the secretion of the pituitary gland; that it may exist concurrently with nasal pathology; that it is wholly independent of this pathology; that it is not relieved by nasal operations, but responds to specific endocrine medication and, finally, that in order to diagnose this type of headache yet render proper treatment . . . . it is absolutely necessary to obtain a complete anamnesis, do a thorough physical examination and employ the laboratory aids requisite."

John T. Halsey (5), of New Orleans, refers to pituitary headache in the following terms: "The frequency with which recurring headache of a peculiar type (bitemporal, very intense, described by the sufferer as boring) was present in patients presenting other conditions suggestive of pituitary disturbance, led Pardee to administer pituitary substance to a series of seven such cases. The results obtained were most gratifying; and in all the cases making up this series, there was marked amelioration or cure of the headache . . . . Glassburg reports that the daily administration of pituitary extract cured several severe headaches of over two years' duration. Dalché reports relief of a headache from the administration of 0.1 gram of dried extract of the whole gland, two to four times daily in a case in which an endocrine upset had induced congestion of the pituitary. Timme and many others have noticed that in many cases of dyspituitarism, relief of headache followed pituitary medication."

I now quote from an important article by Walter Timme (6), in which his opinion of the importance of pituitary headache is quite clear. Referring to a certain feature of a type of cases which he classed as suffering from "a new pluriglandular compensatory syndrome," Timme proceeds: "In our judgment, it is the pituitary gland which is here the critical factor. As we have seen, it is invariably enclosed in a small sella turcica, and possibly even hemmed in by the clinoids . . . . If the pituitary possibly could become hyperplastic and hyperactive . . . . compensation might be accomplished. Such tendency to hyperplasia in a small cavity would, of necessity through pressure, produce headache—an invariable symptom in the third stage of these compensated cases." Timme then proceeds to discuss the other incidental features accompanying enlarged pituitary gland which became manifest in several of the cases under his care, and further on remarks: "Curiously enough, in all our cases, the feeding of the pituitary gland in fairly large quantity disposed of many, and at times, of all of these symptoms." This statement indicates to me that at least a proportion of the dyspituitarism mentioned by this writer, was of a functional character, for it is very well known that the pituitary headache resulting from pituitary tumor is not by any means spectacularly modified for the better by pituitary therapy, or for that matter by any other form of internal therapy.

Perhaps the most masterly article on the whole subject is that by Engelbach and Tierney (7), of St. Louis. A complete consideration of every feature of this disturbance is given and illustrated by a number of clinical experiences. It is evident that they consider the pituitary gland as the victim of circumstances which cause its undue enlargement, and that the pain comes about in the manner already outlined in quotations from other writers.

In that portion of this article referring to treatment (see page 493), it is interesting to note the

effect of treatment on some of their cases. One of these, a physician, aged thirty-one, was given simple thyroid therapy for the first three months of her treatment. This had a beneficial influence upon one feature of her difficulty—she lost nearly twenty pounds in weight. Her headaches occurred less frequently and were not so extremely painful. The dysmenorrhea was not affected. Evidently she developed some symptoms of thyroidism, due to the medication, in consequence of which the treatment was interrupted for several days. Later on, corpus luteum was added to the thyroid treatment for two months, and there was no further improvement in the condition. Then anterior lobe pituitary was added to the thyroid and corpus luteum, and was given by mouth and hypodermically. Soon after this combined treatment was given, the patient began to note marked changes towards improvement. After a month's treatment of this kind: "The patient had the first painless period in her menstrual life. The headaches, nausea, vomiting, nervous disturbances, mental confusion and irritability have disappeared entirely." This pluriglandular treatment was continued for some time further, "with remarkable freedom from symptoms and signs present previous to its administration."

This, to my mind, not merely emphasizes the importance of oral pituitary therapy in pituitary irregularities and especially what is believed to be pituitary headache, but it shows in a most conclusive fashion the value of pluriglandular therapy. Here is a patient—a physician herself—who takes thyroid therapy for months with certain indubitable benefit. Ovarian therapy is added with little or no benefit, but as soon as the combination of the thyroid, ovary and pituitary is given, to repeat the authors' own words "after a month's treatment of this kind, the patient had the first painless period in her menstrual life. The headaches, nausea, vomiting, etc. . . . . had disappeared entirely"—a very decided indication that pluriglandular therapy has some advantages over single gland therapy.

This reminds me of a point let slip by Harvey Cushing (8) in one of his papers on endocrinology which were quite numerous some years ago. In a footnote on page 1724 Cushing, referring to his series of 255 cases of pituitary disease, admits "A great number of these patients have been induced subsequently to follow out prolonged courses of glandular treatment. I cannot say that I have ever seen any definitely beneficial results of so doing except when there has been some concomitant thyroid want indicating the coincidental use of thyroid extract." This, of course, is the basis of all my notions on pluriglandular therapy and is, I believe, fundamental. I should like to ask these respected endocrinologists why they did not start with pluriglandular therapy and save the patients all the pain, expense and discomforts of treatment during the several months during which the single gland extracts were given experimentally?

To return to the importance and reality of pituitary headaches. I think that Dr. Joseph L. Miller's statement must be retracted. Undoubtedly, a number of important writers have contributed their impressions to a literature which will be found in any medical library and indicate that they believe that there is a functional pituitary headache, that this particular headache is due to a temporary enlargement of the pituitary gland and that consequently there is pressure upon the nerves to the dura; and, best of all, that this particular kind of headache very commonly is responsive to organotherapy.

If we believe with Dr. Miller that the only kind of pituitary headache is the one which is due to the pressure of a pituitary tumor, we are going to deny to a very large class of patients—pituitary headache, especially is quite a common symptom in women with menstrual irregularities—the benefit of a method of treatment which is nothing short of specific. In fact, one of the writers (Pardee) just quoted uses this particular term "specific."

After all, my own confidence in this advanced method of treating this condition has come about as the result of my own experience. I have treated at least one hundred cases of pituitary headache in women accompanied by ovarian irregularity. In practically every instance I gave a combination of thyroid, pituitary and ovary. Not in every instance, but in a large percentage of these cases, the headache was cured entirely, many having previously received sedative treatment and headache tablets, and some of them even morphine. I shall never forget the most spectacular of all of these cures: A woman in the late thirties had had headaches for ten years —not a series of headaches, or a tendency to headache, but a headache which lasted, without intermission, for ten years of her life! During that time she had had all sorts of treatment as well as a nasal operation and, I think, some pelvic surgery. The headache was never entirely stopped. During the period of influence of sedatives like morphine, her headache would be dulled and perhaps lost temporarily, but she had a headache none the less, she merely could not feel it for the moment. This patient was cured in three months following this pluriglandular treatment just outlined, and the attitude of this woman following so simple a treatment over so comparatively short a time was such as to make me forever remember the reality of the condition as well as the valuable influence of this treatment.

Unfortunately, it is not possible to treat pituitary headache with success in every case, for it is sometimes difficult to modify the fundamental underlying causative factors, but in fully fifty per cent. of these cases the results are not merely good, but often spectacular, and one has only to meet a few of these women to be assured of the fundamental correctness of the pathologic deduction and the years of clinical work that has been built thereon.

The Mastoid Operation

A Discussion of the Results in One Hundred Cases

JOSEPH FRIEDMAN, M.D.
and SAMUEL GREENFIELD, M.D.
Brooklyn

In studying the results of any particular procedure there are certain distinct and definite requisites necessary if they are to be relied upon and one is to accept the presented data as authentic. First, the number of cases studied must be sufficiently large so that the conclusions drawn will be based upon as wide and varied an experience as is possible. Second, the procedure employed must be similar in all cases, or at least the fundamental and basic principles underlying the operation must be identical. Third, the after-treatment which is of the utmost importance and leads up to the final result desired should be of the same kind and carried out as much as possible under similar conditions. Fourth, the results of the operation should be governed by determining at the time of discharge, the following: condition of the posterior wound, condition of the middle ear, in regard to whether it is dry or moist, the presence or absence of perforations in the drum membrane, and lastly, the state of hearing.

One hundred cases are a sufficiently large number from which to draw some valuable conclusions. The cases were taken as they occurred without any attempt to select them. Of the series we are reporting eighty-one were seen in private practice, and the remaining nineteen were clinical cases. Seventeen of the one hundred were in adults and the remaining eighty-three occurred in children (the patients under seventeen years of age being included in the latter class).

It is not our intention in this paper to discuss the etiology or pathology of acute mastoiditis, but we wish to express our opinion concerning certain observations we have made in the past few years that have special bearing upon the course of the disease. Whether in a given patient with acute suppurative otitis media, a mastoiditis will develop depends not so much upon the physician nor upon the treatment, but upon the anatomical conformation of that particular patient's attic, antrum and mastoid process, and upon the type and virulence of the infecting microorganisms. It is purely and simply a question of drainage facilities that determine the outcome of any given case. It is a known clinical fact that ears will rupture spontaneously and go on to complete recovery. On the other hand cases will run a similar course, the ears opening of their own accord and finally terminate with an operative mastoid. Then again patients will come to us with well established acute otitides—red angry bulging drums, we incise, obtain pus, and prescribe the usual irrigations. The discharge continues for from one to three weeks and gradually subsides with complete recovery. On the other hand we get an early case of forty-eight to seventy-two hours' duration; there is distinct bulging; the child has severe pain and rise of temperature; we incise, obtain pus, prescribe the same irrigation and the child goes on to the development of a mastoid abscess. In these children who eventually come to the operating table their acute otitis begins with a simultaneous involvement of the mastoid cells. By this we do not mean the mild involvement that we see in many cases the first few days of the acute otitis. With an inflammation of the middle ear the contiguous mucous membrane of the mastoid cells is also sympathetically inflamed, but with the establishment of drainage this gradually subsides. Tenderness over the mastoid process, particularly in the region of the antrum, and even spontaneous pain occurring the first few days of the middle ear suppuration are of little importance. It is only when these symptoms referable to the mastoid persist, especially after the drum has been incised and drainage well established, that they begin to assume some importance.

It is therefore our opinion that all cases of mastoiditis which are associated with suppurations of the middle ear are not complications of the latter condition, but are concomitant inflammations that originate at the same time; in other words, mastoiditis should not be reckoned as a middle ear complication. A mastoiditis is a mastoiditis from the moment the otitis begins, and cannot be prevented. For this reason in cases that often receive the utmost care and attention, where early and adequate incision is made, where proper cleansing of the secretions is strictly adhered to, and where the child is given all possible general support, the patient is obliged to submit to operation despite all these measures.

It is not our desire to disparage early incision of the drum membrane where indications are present, nor to urge against any of the well founded and logical measures constituted in the aftertreatment of such cases. We must use every possible effort to aid the patient in overcoming the infection, for as in all other acute inflammations, with the establishment of proper drainage facilities—and this can only be hoped for in cases where the anatomical conformation of that particular patient's attic and antrum will permit of such drainage—the condition can subside and the patient go on to complete recovery.

In all our cases we have been rather conservative in advising operation upon the mastoid. The patients were carefully observed and every possible opportunity given them before we decided to interfere. In adults particularly we waited until we were pretty well assured that spontaneous recovery was improbable. Great stress was laid upon the late tenderness and pain in the mastoid, that is to say, patients who so complained during the third and fourth week of the disease, even with a fairly good looking middle ear, we urged operation and we can truthfully state that in every case falling into this category we found ample disease and necrosis in the mastoid. In summing up the indications for operation we took into consideration the following points.

TENDERNESS OVER THE MASTOID

This tenderness is elicited upon palpation over the mastoid process and is due to direct pressure against inflamed tissue. Of all signs and symptoms of mastoid disease this is the most constant and reliable one in determining operation. The acuteness of this tenderness varies in different individuals but as a rule its intensity is an indication as to the severity of the mastoid disease. Sensitive patients, however, are likely to complain more than others and this must be taken into consideration, especially in children. Of great importance is the tenderness that persists during the second and third week. As has been pointed out before, the early tenderness which occurs in many cases during the first few days usually disappears at the end of a week. It is the persistence of this tenderness that is of such great importance. The location of the tenderness varies. It may be over the region of the antrum, over the tip, over the posterior group of cells, or over the premastoid lamina. In most of our cases the region of the antrum seemed to be the point of election. However, tenderness need not be present and its absence does not preclude mastoid disease, for in cases with a very thick cortex or with a forward sinus with few or no cells between it and the cortex pain upon pressure may be absent.

SPONTANEOUS PAIN IN THE MASTOID

This is due to actual active inflammation of the bone and its mucoperiosteum and as in all bone diseases the pain reaches its acme of severity at night. It is not present in all cases. As a rule it is associated with tenderness, although the latter may not be accompanied by it. In children it manifests itself by restlessness and irritability during the day, and sleeplessness at night. The pain need not be localized over the mastoid itself but may be referred to any part of the head on the same side. It may be parietal, occipital, and even frontal. Characteristic are the lancinating, shooting pains across the head originating in the region of the mastoid and radiating up over the parietal or back to the occiput. The pains seem to be more severe in those cases in which there is disease of the dural or sinus plates.

THE CONDITION OF THE MIDDLE EAR AS GOVERNED BY THE APPEARANCE OF THE DRUM MEMBRANE

At the end of the second week there should be evidences of beginning resolution. A case in which the drum is boggy, edematous, and thickened is not doing well. The drum membrane appears to be prolapsed and from beneath the prolapse one notices the escape of pus. We are likely to believe that this bulge is the result of pus under pressure but repeated incision does not confirm this, for the drum bleeds profusely and our incision fails to yield pus. The presence of granulation tissue speaks against a speedy recovery. The location of the perforation is of great significance. We wish to emphasize that the condition of the middle ear as evidenced by the appearance of the membrane tympani is not always a criterion of what is going on in the mastoid process. It is true that our opinion in a suspicious mastoid receives confirmation when the otoscopic appearance of the middle ear is commensurately poor. Nevertheless there are cases in which we have good looking middle ears, even to the extent that resolution is well established and yet the mastoid involvement has progressed to a state where surgical intervention seems imperative. It is just such cases in which we find a narrow attic, that in the course of the disease the communication between the middle ear and the antrum becomes obliterated either through lodgement of a plug of pus, exudate, or newly formed granulations. The middle ear because of adequate drainage goes on to complete resolution, even with closure of the perforation in the drum membrane. The infectious process in the mastoid, however, continues and eventually calls for operation. Then there are those cases in which the causative microorganism is the insidious Streptococcus mucosus capsulatus, first described by Neumann and Ruttin, in which the middle ear may be practically normal, without perforation, discharge, or redness and with few or no mastoid manifestations. This organism has a faculty of avoiding the middle ear, lodging directly in the mastoid cells (1). The first symptom that directs our attention to the existing condition is the appearance of a postauricular swelling, a sign of already well advanced suppuration of the mastoid. We have seen two such cases in our series, one occurring in a member of our own family, in whom both mastoids followed this course just described, and in which the streptococcus was recovered in pure culture from the pus at operation. Rae believes that in all these cases there must be a middle ear stage occurring often several weeks before the onset of the mastoid symptoms. In one of our cases we obtained such a history—the child having complained of pain in one ear for a period of several days—three weeks before the appearance of the postauricular swelling. The pain disappeared and no aural discharge was noted at any period. At the time of operation the otoscopic picture was practically negative. Dixon (2) goes so far as to advise exploratory operations in all cases in which the streptococcus has been obtained from the discharge of the middle ear, if the discharge persists even in the absence of other symptoms of mastoiditis.

SAGGING OF CANAL WALL

Sagging of the posterior superior canal wall is an important finding. It is due to periostitis causing edema of the floor of the antrum and attic. Its presence coupled with other signs makes mastoid involvement very probable. Nevertheless in very young children its importance we feel has been overestimated. Cases with sagging can clear up and this is a positive clinical observation (3). In adults, however, it is of the utmost importance.

AMOUNT OF DISCHARGE

A discharge no matter how profuse in the early days of the disease can eventually cease with complete recovery. It is not so much the amount of discharge that flows out of the middle ear that concerns us, but whether or not it shows a tendency to diminish. A profuse discharge late in the disease points to the involvement of a larger surface than is contained in the middle ear cavity.

TEMPERATURE

Uncomplicated cases of mastoiditis have little or no rise in temperature. Its presence in adults often signifies some other complication. Having ruled out

all other possible general sources for its presence only then are we justified in attributing it to some otitic complication. In view of the fact that a simple acute suppurative otitis media in children will be accompanied by fever (4) and with mastoid involvement will protract a higher febrile reaction, it is a difficult matter to determine how much of the fever is due to the otitis, and how much of it is the result of the superimposed mastoid disease. Persistent high temperature which does not yield to the more conservative measures does call for interference. In general it may be said that the temperature alone should not be taken as an indication for operation for it is a poor index as to what is going on in the mastoid cells. In most of our cases there was little or no temperature. In some, with practically no fever, we found the mastoid extensively diseased.

X RAY

In young children röntgenological examination of the mastoid is of practically no value. In some adults, however, where we are undecided this will prove a valuable aid in the diagnosis. A good röntgenologist is of inestimable value to the otologist.

GENERAL CONDITION OF PATIENT

Where a patient is doing well generally we can take plenty of time to study our case before we come to a definite decision to interfere. However, an uncomplicated case of mastoiditis should not be very much affected systemically. These patients practically all suffer from anorexia, malaise, have a coated tongue and it is to be expected. Where there are evidences of greater systemic disturbances we are dealing with some complication.

DURATION OF DISEASE

It can readily be understood that the duration of the disease modifies greatly the value of those points enumerated above. The later in the disease these signs and symptoms appear, or rather the longer they persist, the greater their significance as evidence of mastoid disease. Few patients with the exception of those with subperiosteal involvement, were operated upon before the third week. In young children, when in doubt we advised waiting for a swelling. In several adults we advised operation the second week, but in these cases the patients presented classical pictures and we dared not procrastinate, for spontaneous recovery seemed improbable. It is a difficult matter to attempt to put a time limit and be guided simply by the number of days or weeks that the illness exists. Some advocate operation in all cases in which the discharge persists more than six weeks (5). We cannot share this opinion. With absence of other symptoms the discharge itself is not a sufficient indication for operation at this time. We have all encountered cases that discharged eight and ten weeks and conservatism has been rewarded with complete recovery.

SYMPTOMS OF A MORE SERIOUS COMPLICATION

As soon as a definite diagnosis is made the mastoid should be opened. Politzer (6), however, advocates waiting until the eighth day before interfering unless there are symptoms of meningeal irritation. Delay simply increases the possibility of such complications. Furthermore, it should be remembered that we cannot measure the extent and severity of destruction by outward manifestations. It is therefore the endeavor of the otologist to recognize these possible dangers and so avoid sequelæ that can justly be attributed to undue and unnecessary procrastination. Briefly, in a suspicious mastoid those manifestations that indicate possible extension of our inflammatory process in the mastoid to more important structures and call for immediate operation are: symptoms of meningeal irritation; persistent high fever, or a septic type of temperature, the source of which cannot be accounted for elsewhere; persistence of severe headache; recurrent chills and sweats; paralysis of the external rectus (Gradenego); paralysis of the facial nerve; signs and symptoms of vestibular irritation, such as vomiting and nausea and increasing evidences of a general infection or toxemia.

CASE HISTORIES

We wish to cite briefly several cases which will emphasize the importance of those indications we have outlined above.

The significance of remittent temperature will be appreciated from the following histories. In one case with a running ear two weeks, because of a temperature ranging between 99° and 105° F., we suspected a sinus thrombosis and upon operation found a thrombosis of the lateral sinus and mastoid emissary. In another instance a child eleven years old came to us in the fourth week of the disease, with a temperature that was fairly constant and not of a remittent nature, ranging between 102° and 105° F. He was pale and anemic, haggard looking, with an expression that was drawn and sickly—the patient apparently was suffering from severe septic process. This case was reported by us (7). At the primary mastoid operation we found a necrotic sinus filled with pus.

The significance of severe headache was demonstrated in a patient forty years of age, in the third week of the disease in whom we suspected a mastoid and advised operation. The patient refused and several days later he began to suffer from most excruciating headache. The pain on one occasion became so intense that he made an attempt to leap from his bedroom window. At operation this patient had an extensively diseased tegmen antri with a large epidural abscess.

A case reported by us (8) in a boy aged nine who sustained a fractured skull presented an acute mastoid ten days later. In this patient severe headache was a prominent symptom, not originating from the fracture, but from a large perisinus abscess. At operation we found the sinus plate necrotic, the sinus covered with granulations.

In one case there occurred a Gradenigo before operation. This patient was seen in conjunction with Dr. Friesner. During the fourth week of an otitis complicating scarlet fever a paralysis of the external rectus on the same side was noted. In addition there was slight mastoid tenderness, a poor otoscopic picture and the child complained of headache. At operation we found a mastoid containing diseased granulations, but no free pus. There was softening about the tegmen and the dura was exposed, but nothing abnormal noted.

(To be concluded)

Dental Infections and Heart Irregularities*

S. CALVIN SMITH, M.S., M.D.
Philadelphia

The clinical relation between tonsillar infection and heart disturbance was so generally recognized by earlier medical generations than ours that it is today a universal teaching that signs of heart involvement should be looked for during acute tonsillitis, rheumatic fever and chorea. Unfortunately, the clinical relation between alveolar abscess and heart abnormality is not so generally appreciated by the medical profession. Yet one infection is of as much importance as the other to the practising physician who is confronted with the necessity of investigating every circumstance that might be responsible for defective heart action among his patients.

DENTAL INFECTIONS MAY BE SYMPTOM FREE

There are several reasons that may be advanced to explain the failure of physicians generally to recognize the relation between dental defects and heart disturbances. To begin with, the idea is comparatively new. It was in 1910 that Sir William Hunter, at McGill University, first called the attention of physicians to the important subject of oral sepsis. Sir William's paper profoundly influenced dental thought and has been credited with being a prime factor in evolving the modern school of dentists who, by their progress in relieving the cause of some systemic diseases, have earned a right to a title more comprehensive than dental surgeons: they are in truth dental clinicians. Medical practitioners, during the same period of time, continued to follow their established custom of giving more attention to the treatment of acute conditions; and as periapical infections of the teeth are for the most part chronic in nature and usually symptom free, such infections frequently escape the notice of physicians today.

A third reason might be found in the skeptical attitude which medicine traditionally adopts towards any clinical premise that does not readily lend itself to being established by methods of scientific proof—although such a reticence towards admitting the possibilities of dental infection is scarcely consistent with the rush to embrace glandular therapy nor with the proposed wholesale dosing of the public at large with iodine.

There is, however, a logical sequence existing between cause and effect. Should an irregular heart become regular following the removal of peridental abscesses, one such single instance might be accounted a happy accident of chance. But when a similar sequence of events pertains repeatedly, and the previously harassed heart thereafter persists in acting normally, then clinical experience has grasped a truth with which scientific analysis would do well to catch up.

THE CAUSES OF HEART IRREGULARITIES

Among office patients, cases of irregular heart action can often be attributed to such causes as fatigue, anxiety, endocrine imbalance, gastrointestinal disturbances, faulty heart nutrition (as in blood impoverishment), to acute diseases, chronic systemic diseases, cardiosclerosis (as in persons of advancing years), to probable "fatty" heart (as in ponderous people who are confirmedly overweight), to infective tonsils and to the unguarded intake of drugs and other poisons. It is also true that irregular heart action in some patients can be attributed to absorption of toxins from peridental abscesses, as will be shown in the clinical experiences recited and illustrated in this article.

CIRCUMSTANCES OF STUDY

The four cases here presented have many features in common.

1. All of the irregular hearts became perfectly regular after the removal of peridental abscesses.

2. No other form of treatment whatever was employed in these patients: no drugs were given; the periods of physical rest were not even increased nor were customary activities curtailed.

3. Comprehensive physical examinations and routine clinical laboratory studies failed to reveal any abnormal conditions that might account for the irregular heart other than the coincident peridental abscesses.

4. The dentoradiograms in all cases were made by one röntgenologist; each x ray finding was confirmed by a clinical examination of each patient's mouth, conducted by a consulting dental clinician.

5. Heart irregularities will frequently disappear shortly after surgical procedures, for the reason that

*Cardiographic confirmation of probable cause and effect.

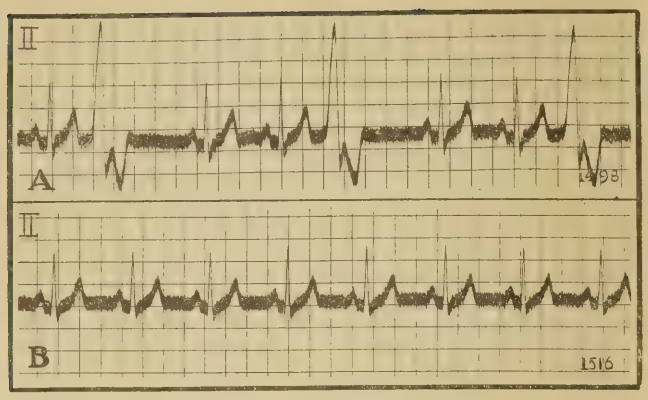

Fig. 1, Case I.—Upper record shows three irregular heart beats caused by premature systoles (originating in the right ventricle). Three weeks after the removal of six alveolar abscesses, the heart action became perfectly regular, as shown in the lower record.

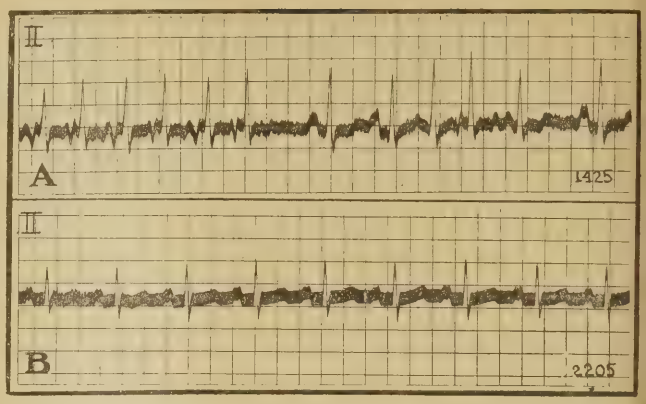

Fig. 2, Case II.—Upper record shows several irregular heart beats caused by premature systoles (originating in an auricle). Five alveolar abscesses were removed and two years later the heart action became perfectly regular, as shown in the lower record.

any circumstance which increases the heart rate will usually cause irregularities to diminish or disappear. Of course anesthesia stimulation or wound absorption increases the heart rate. Therefore, in order to avoid the obvious deduction of temporary stimulation improvement, in this series the heart records exhibiting improvement were not taken until sufficient time had elapsed, following dental relief, for the heart to be persistently regular—the intervals being from three weeks to two years.

6. Premature systoles—which are variously termed extrasystoles, dropped beats, intermittent pulse, and other names—is the type of irregularity which has been chosen to illustrate this group of cases. This irregularity is so graphic that he who runs may read the disturbance in rate and the break in rhythm which premature systoles induce—an irregularity that is in striking contrast with the returned to normal records that are as rhythmical and regularly recurring in design as a Greek fret.

SYNOPSIS OF CASES

Case I.—A muscularly powerful man of forty years, of the stocky, athletic type, was rejected by an insurance company on account of a frequently irregular heart action.

The cardiophysical examination revealed no abnormality other than the irregularity which was constant under all circumstances of test, such as before and after exercise, when mentally stimulated and when dozing. The cardiographic records proved the irregularity to be due to premature systoles originating in the right ventricle (Fig. 1).

Four of the patient's teeth contained large central fillings, and dentoradiograms revealed rarifactions at the apices of all four, as well as at the roots of two other teeth which had not been clinically suspected.

The patient, indiscreetly, had all six teeth removed at one sitting; fortunately, there was no untoward physical reaction following such wholesale extraction.

Within ten days the irregularity diminished and after three weeks the heart action became perfectly regular and has remained so to date, over a period of two years.

Case II.—A jurist, sixty years of age, was referred by an exodontist who declined to operate until he knew the type of irregular pulse which the patient presented.

The cardiophysical examination revealed a pulse frequently irregular but interspersed with periods of very rapid, regularly recurring beats, a definite increase in the transverse diameter of the heart and there were râles at the base of the left lung posteriorly. In the patient there was developing shortness of breath on accustomed effort, he became lightheaded on sudden change of posture and was readily fatigued.

The cardiographic records proved the irregularity to be due to premature systoles arising in an auricle (Fig. 2); at times these premature systoles occurred for many successive beats, thus inducing periods of true paroxysmal tachycardia of auricular origin.

Five of the patient's teeth on x ray examination were found to have rarefactions at the apices. After extraction these teeth were examined bacteriologically and the cultures were found to contain Streptococcus viridans. While marked clinical improvement followed dental extraction within six weeks, the irregularity showed no change for six months; it then steadily diminished in frequency and two years later the heart action became perfectly regular.

Case III—A robust mining engineer of twenty-nine was referred for cardiovascular study because the rate of the heart was 80 beats a minute, while the radial rate was only 40 beats a minute.

The cardiophysical examination sustained these findings, but revealed no additional abnormality. The patient complained of shortness of breath, early fatigue and precordial distress.

The cardiographic records proved the radial deficit of 40 beats to be due to premature systoles which alternated in regular occurrence between normal beats. The premature beat occurred so closely following a regular beat, that the ventricle did not contract on an amount of blood sufficient to lift the aortic cusps, and thus failed to propagate a pulse to the wrist. This regular recurrence of an irregularity (Fig. 3) persisted under all circumstances of test.

Four of the patient's teeth, on x ray examination, were found to have rarefactions at the apices. These four teeth were removed, and four months later the irregularity had diminished perhaps thirty per cent. The patient decided to have a fifth tooth removed which was centrally filled. A large granuloma was found attached to the root, but had not been revealed by the x ray. One year following

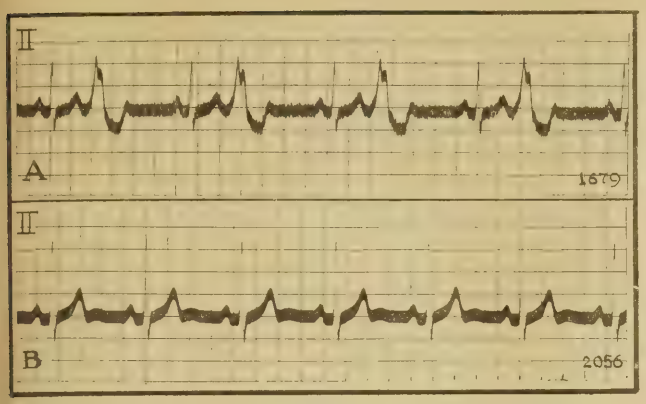

FIG. 3, Case III.—Upper record shows four irregular heart beats caused by premature systoles (originating in the right ventricle). One year after the removal of six alveolar abscesses, the heart action of this patient became perfectly regular, as is shown in the lower record.

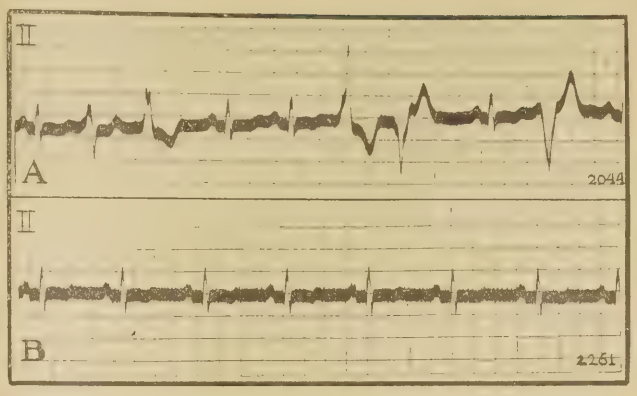

FIG. 4, Case IV.—Upper record shows five irregular heart beats caused by premature systoles (originating in the tissue between the right auricle and ventricle). Three months after the removal of four alveolar abscesses, the heart action became perfectly regular, as shown in the lower record.

the original dental extractions the heart action became perfectly normal.

CASE IV.—A slender delicate woman of perhaps thirty-five years complained that she was unable to play tennis on account of violent thumping and skipping of her heart, which produced pain in her chest. The cardiophysical examination revealed no abnormality other than the irregularity above mentioned. The patient was steadily growing shorter of breath, she tired easily and had intervals of faraway sensations.

The cardiographic records proved the irregularity to be due to multiple premature systoles, originating in the node which is situated between the right auricle and ventricle (Fig. 4).

Four of the patient's teeth contained large central fillings, and dentoradiograms revealed slight rarefactions at the apices. The idea of dental extraction was repugnant to the patient and she declined to have the suspected teeth removed. For three months she was confined to her home as a cardiac invalid, temporizing with what proved to be one therapeutic fantasy after another. In desperation, the four suspected teeth were finally extracted, and within three months thereafter the heart action became perfectly regular.

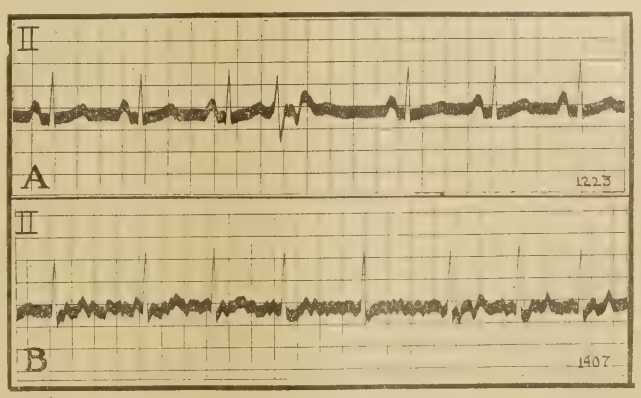

FIG. 5, Case V.—Upper record shows a single irregular heart beat caused by a premature systole (originating in the right ventricle). Dental x rays indicated that two alveolar abscesses were present, but they were not removed. Four months later profound heart damage ensued, as evidenced by the total irregularity of auricular fibrillation shown in the lower record.

CASE V.—A physician of mature years and extensive clinical experience requested cardiovascular survey for what he termed "an extrasystolic arrhythmia."

The cardiophysical examination revealed no abnormality other than a very occasional irregularity. The patient complained of tiring easily, of growing mentally sluggish and his gait and actions were hesitant.

The cardiographic records proved the irregularity to be due to an occasional premature systole originating in the right ventricle (Fig. 5).

Two of the patient's teeth, which were abutments for dental bridge work, were found by dentoradiographic study to have rarefactions at the apices. He stoutly declined to part with these probably infective roots, on the absurd reasoning that their removal would necessitate a complete set of teeth for the lower jaw.

Four months later the premature systoles had disappeared, but in their place was substituted the absolutely complete irregularity of auricular fibrillation, which, having once started in a person of his years, will likely become permanently established, despite any efforts at relief.

THE HEART MUSCLE SIGNIFICANCE OF PREMATURE SYSTOLES

As previously stated, the irregularities discussed in this paper are confined only to premature systoles. It is appropriate for us to inquire at this juncture, what may be the heart muscle significance of premature systoles? They are seriously regarded when they occur during the course of an acute illness; but in persons otherwise healthy who are up and about the premature systole is often disposed of with a gesture of inconsequence. We all know that this type of irregularity in some patients seems to be quite harmless, and this seems to be the accepted view, judging from the number of patients who in the past have been told "oh your heart is all right—you have just a dropped beat occasionally."

I am quite in accord with the idea that an occasional premature systole, by itself considered, is not indicative of actual structural heart muscle defect. On the other hand, this seemingly simple, occasional heart irregularity has been known to proceed with almost lightninglike rapidity to a multiple frequency where it interfered with the proper distribution of the

blood supply, and from that improper distribution, symptoms of heart failure have ensued and the patients have become cardiac invalids. It has also been noted that the seemingly simple irregularity may at any time change into a more serious type of heart irregularity, such as auricular fibrillation. Hence it is not only unscientific but actually unsafe to reassure a patient with the statement that "you have only extrasystoles." Too often it is a warning signal of heart protest. It is our duty to search for the underlying cause which makes the heart display the danger signal of irregularity. Such a search should not fail to include x ray and dental study of the teeth, for a symptom free abscess may be hidden and unrecognized at the apices of any one of the forty-six roots in the jaws.

A SIGN THAT INFLUENCES THE PROGNOSIS IN PREMATURE SYSTOLES

When attempting to appraise the clinical significance of premature systoles, an aid of considerable diagnostic importance can be found in the behavior of the irregularity before and after exercise. A premature beat that is present during periods of rest and which *disappears* when the heart rate is speeded up by mental, emotional or physical activity is, I believe, more indicative of *toxic* heart disturbance than of actual structural (organic) heart muscle involvement. On the other hand, when the irregularity *increases* in frequency following mental, emotional or physical activity, I believe it safe to regard such behavior as indicative of *structural* (organic) heart muscle involvement. If this sign has been previously described, I am not aware of it.

From these observations it is evident that the premature systole which is of toxic origin is quite likely to disappear when a toxic cause is found and removed. It is also equally evident that premature systoles which are probably due to structural heart muscle defect will not disappear with the removal of a toxic cause. But let us bear in mind that the search for and the removal of a toxic source, even in a permanently damaged heart, may prevent that heart from becoming progressively worse as the years advance. Therefore, in a patient in whom premature systoles occur, the removal of a toxic source may prevent additional heart defect in the future life of that patient, and affords us some assurance that a damaged heart will retain such efficiency as is compatible with the age of the subject.

SUMMARY

1. Heart irregularities will sometimes disappear when peridental abscesses are identified and surgically removed.

2. The x ray is of assistance in identifying peridental abscesses, but it cannot supplant thorough clinical examination and exhaustive tooth vitality tests at the hands of a modern dentist.

3. A dentoradiogram that fails to show rarifications should not lead the physician to absolve the teeth from blame when tracing the cause of heart abnormality. Clinical dental examination is necessary.

4. Should a dentoradiogram present suspicious rarefactions, the accused teeth should be subjected to a clinical dental examination.

5. A peridental abscess which is determined to be present by x ray and by clinical studies admits of no compromise. That abscess should be surgically removed, even though the removal of the abscess means the removal of the tooth. It is unscientific to assume that an abscess can be treated through a small opening in a tooth and thus rendered harmless permanently. The physician who has charge of the health of a patient should not countenance such a temporizing maneuvre which is always inimical to and very frequently jeopardizes the heart integrity of that patient.

6. The form of heart irregularity which occurs with the greatest frequency in association with periapical dental abscesses is the irregularity known as the premature systole. In the general run of patients who are concerned about their hearts and who as yet are not in any sense cardiac invalids, the premature systole is the irregularity most likely to be present.

7. A study of the heart is incomplete without radiographic and clinical studies of the teeth.

Influence of the Soft Parts Upon Blood Pressure

CLEMENT B. MASSON, M.D.
New York

While studying blood pressure of the brachial, femoral, and posterior tibial arteries in cases of aortic regurgitation, the question arose whether or not there were discrepancies in the high systolic readings in the thigh just above the knee. Together with the sparsity of experimental data in the literature this led to the following investigations to determine what effect the soft parts of a limb have upon its blood pressure determinations.

Janeway (1) quotes Von Recklinghausen who demonstrated that with a sufficiently wide arm piece the size of the limb and the degree of its development made no difference in the accuracy of blood pressure readings. Muller and Blaud made direct pressure determinations in three operative cases and found them nine to ten mm. less than readings taken with the cuff. The narrow arm piece and Gartner's method made large errors. Henson had a case of marked muscular atrophy of one arm, but the pressure in both was the same.

Janeway cites two cases demonstrating that the factor of soft parts does not have any effect. Discrepancies between clinical blood pressure estimations and direct manometric readings from the same limb must be explained either by resistance to compressior of arterial wall or by errors in readings.

Case I.—Carpenter, fifty-seven years of age, cardionephritic, one arm measured thirty cm. in circumference, the other arm (flaccid) 21.5 cm. in circumference. Blood pressure in both 300/180 mm.

Case II.—Lumberman, fifty years of age, a 331 pound man whose arm measured thirty-nine cm. in circumference, had a systolic pressure of 115 mm.

Cabot (2) says, "It is true that the air within the rubber armlet has to overcome not only the pressure within the radial artery but the resistance of the artery wall and the elasticity of the soft parts around it." The former factor has been shown to represent a pressure of not more than two to three mm. mercury provided the artery walls are normal. If arteriosclerosis is present, it has been estimated by Herringham that the artery may oppose a resistance of fifteen to twenty mm. mercury. The more carefully conducted experiments of Janeway, however, show that Herringham is wrong and that sclerosed arteries offer a direct resistance of less than five mm. mercury. The amount of error this introduced is not of importance.

The resistance of the soft parts around the artery is a factor of no importance provided the compressing armlet is at least twelve cm. wide. A large arm gives no higher reading than a shrivelled one, as has been shown by Janeway in a patient, one of whose arms was congenitally atrophied while the other was enormous.

In this experiment the first five cases with normal cardiovascular systems showed no very appreciable increase in blood pressures as compared with the quite marked difference in size of soft parts. All blood pressures were taken with the patient in a prone position. The last three were known to be cases of aortic regurgitation and as one would expect, the systolic pressure in both the thigh and leg were increased over that of the arm, but not in any definite proportion to the size of the soft parts in the respective limbs. These facts would seem to indicate that the soft parts do not play any part in affecting blood pressure readings, in either the arms or legs. In a series of twelve cases free from aortic regurgitation and aortic aneurysm, blood pressures on the arms and legs were taken with the patient in a prone position. All showed readings similar to the first five cases noted above, i. e., there was a rise from five to twenty points noted in the systolic pressure of the femoral over that of the brachial artery, but the diastolic pressure in the femoral artery always equaled that in the brachial artery.

However, to investigate further the effect of the soft parts of a limb upon blood pressure, the following experiment was devised so that the same limb might be used but the size of the soft parts changed in each case and withal closely approximating conditions in nature.

A piece of skin with fat attached was dissected from a freshly amputated leg above the knee. It measured 31.2 cm. by 17.5 cm. weighing 850 grams. By means of a single wrapping with thin brown rubber dam secured at the free edges with narrow strips of adhesive plaster, the exact nature of the poultice remained an unknown quantity to the patient upon whom it was used. The posture of the patient while the three readings were taken in each case remained the same, either in an erect position, prone, or leaning against a backrest.

A STUDY OF BRACHIAL BLOOD PRESSURES WITH REGARD TO A VARYING SIZE OF SOFT PARTS.

2.	32	90/55	26.2 "	100/60 37.5 "	100/62
3.	26	120/70	25.5 "	120/65 36.7 "	125/75
4.	15	105/55	17.5 "	115/65 31.2 "	110/60
5.	27	100/70	28.7 "	110/75 38 "	110/70
6.	29	100/60	27.5 "	105/65 37.5 "	105/65
7.	31	115/60	22.5 "	120/65 34 "	115/60
8.	31	120/35	26.2 "	120/35 37.5 "	120/35
9.	50	180/100	26.2 "	170/90 35 "	170/90
10.	12	80/40	17.5 "	90/45 31.2 "	85/45
11.	11	85/35	18.7 "	90/45 32.5 "	85/40
12.	66	110/60	22 "	120/70 33 "	110/60

In this experiment quite striking results were obtained as can be seen from the accompanying table. Ten points in both systolic and diastolic pressures was the greatest increase with the use of the pad of fat wrapped about the arm. In the first case the arm was made twice as great in circumference and yet the blood pressure reading was only ten points higher in both systolic and diastolic readings. In one case it was lower, in another it was exactly the same and in the remaining the difference was negligible. This can be explained only by the fact that animal tissue is composed of cells containing fluid which transmits pressure equally in all directions, a hydrostatic pressure, and that thus, a large arm or leg will give the same blood pressure readings as a small one in the same individual. In conclusion, then, blood pressure in the arms and legs is the function of the resistance of vessel wall (which is taken to be slight), vascular tonus and cardiac systole, and, as such is read for clinical purposes accurately by

means of a mercury manometer no matter what the size of the limb may be provided the arm band is of sufficient width.

Hence, this experiment is of practical importance to the clinician for it has been proved that the size of a limb does not materially alter its blood pressure. Especially is this of value in taking readings in cases of aortic regurgitations in the thigh above the knee where limbs of greatest circumference are encountered.

Calcified Pericardium Occurring in a Patient with Peptic Ulcer*

Report of a Case

CLARENCE W. RAINEY, M.D.
Chicago

Case.—Mr. W. W., thirty-nine, a chauffeur, was admitted to the medical ward of Michael Reese Hospital February 4, 1924. The chief complaint was epigastric pain of five weeks' duration. There had been four previous attacks of similar nature beginning in December, 1922. The attacks came at irregular intervals of a few months and lasted from three to six weeks. The pain was of a burning character, and often seemed like "a sponge swelling up." The analysis of a typical day revealed the fact that there was no distress when the stomach was empty, but that the distress followed immediately after food taking, and that it radiated up the esophagus.

Associated with the epigastric distress were dizziness and fainting spells. Loss of weight of sixteen pounds in five weeks had occurred. There were slight productive cough and shortness of breath on exertion, and occasionally precordial pain.

In the past the patient had had measles, scarlet fever, chickenpox, tonsillitis, influenza three times, and frequent colds. There had been an operation for bilateral inguinal hernia. The family history was negative.

Physical examination revealed a male, well developed and nourished. The pupils were negative. The lungs were negative. The apex beat was not visible or palpable. No cardiac enlargement could be detected on percussion, and there were no murmurs or adventitious sounds. The pulses were equal, regular and synchronous with the apex sound. The abdomen, extremities and reflexes were normal.

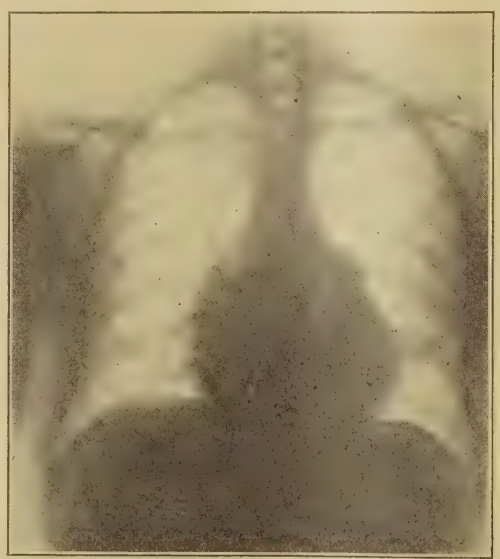

Fig. 1.—Radiograph showing calcified pericardium.

The blood examination showed a hemoglobin of seventy-five per cent. and normal white, red, and differential counts. The blood pressure was 120 systolic, 100 diastolic. The Wassermann reaction was negative. The urine contained a slight amount of albumin. The stools showed no blood. Ewald and motor meals were within the range of normal findings. The sputum was negative for acid fast organisms. The electrocardiogram was negative.

The report upon the röntgenological examinations by Dr. R. A. Arens is as follows: "The heart appears pathological, taking on the globular appearance of a pericarditis. The pericardium apparently contains dense material, which appears to be calcified deposit. Both lung fields show no special pathological condition. The diaphragm is sharp and clear and the angles are free from fluid. The films confirm the fluoroscopic finding of calcification of the pericardium. Röntgenological examination revealed a defect of the duodenal bulb."

In the hospital the epigastric distress, which was the complaint which brought the patient to the hospital, disappeared under dietary and alkaline therapy. He was discharged on March 2, 1924, but was admitted four days later with symptoms of bowel irritation and tenesmus, which disappeared upon adjustment of the alkaline therapy.

While the symptoms were not absolutely typical of peptic ulcer, the presence of positive röntgenological findings for duodenal ulcer, and the fact that the epigastric distress was relieved by ulcer management indicate that the diagnosis of duodenal ulcer was correct. It is probable that the chief complaints were due to the duodenal ulcer, rather than to the condition of the pericardium.

Concerning the probable etiology of the calcified pericardium there are at least two possibilities. The first, that it may have been due to a tuberculous polyserositis, may be dismissed because of lack of confirmatory findings. The second, that the calcified pericardium may have been the result of an acute pericarditis followed by fibrosis and adhesion at the time of one of his numerous previous illnesses, seems probable.

Pulse and Blood Pressure Variations During Exercise and Their Bearing on Myocardial Efficiency

GEORGE H. ROBERTSON, M.Sc., M.D., Ch. B.
Wanganui, New Zealand

This work was begun while I was in charge of the D. A. H. centre, Featherston Military Hospital, New Zealand, and carried on later at the Trentham Military Hospital. Patients suffering from D. A. H. present many subjective symptoms, the effort syndrome of Lewis (1), but few objective signs, and it was desired to devise some means whereby patients admitted with this diagnosis could be tested and classified objectively.

Observation of blood pressure and pulse changes during and after a measured exercise was undertaken and from these a general measure of the condition, and, more particularly, of the cardiac reserve power, obtained.

At the outset a word of warning is necessary. As pointed out by Norris (2), blood pressure methods of determining circulatory efficiency "are based on sound theoretic principles and would be invaluable if our instrumental methods were sufficiently exact and comprehensive . . . unfortunately, however, the data obtainable by sphygmomanometry are, even when collated with the utmost care, subject to unavoidable sources of error."

This has been recognized, and in this paper no elaborate arithmetical calculations have been attempted, nor has there been any endeavor to reduce blood pressure and pulse relationships to an algebraic formula. I estimate that in my own readings the limit of error in records of pulse rate is plus or minus four; in records of systolic pressure, of plus or minus two; in records of diastolic pressure, of plus or minus four and a half. As will be noted subsequently in this article these possibilities for error do not destroy the value of the work done, nor invalidate the conclusions drawn.

A further objection is pointed out by Dr. G. A. Sutherland (3), who discussing cardiovascular debility in aviation candidates, remarks that the myocardial factor is not the only one concerned in pulse and blood pressure changes during exercise, and that the main factors to be considered are these: effects of exercise upon 1, the cardiovascular system; 2, the respiratory muscles; 3, the muscles involved in performing the particular exercise; 4, the pulmonary organs, and 5, the nervous coordinating and controlling centre. Again, Ch. Laubry (4) refers to work on this subject by many French investigators and concludes that "tachycardia and arterial tension result from conditions too numerous to draw from their variations an absolute conclusion on the functional capacity of the heart."

This is freely conceded, but it must be observed that these same and differing factors are concerned also in the patient's performance of his everyday work and that the test of exercise tolerance is really designed to investigate his capacity for doing work. In the carrying out of that work a first necessity is the maintenance of an efficient blood supply to the tissues, and the tests carried out give an indication of the power of the subject, acted on, if you will, by all five forces mentioned above, to produce, and to maintain, such an efficient blood supply.

The inspiration for the work undertaken in the present investigation, and suggestion as to the manner of its being carried out, came in greater part from an article by Dr. J. Strickland Goodall (5) entitled The Estimation of Myocardial Efficiency. This article is based on the assumption "that the measure of a heart's efficiency is its capacity for doing work."

Goodall describes four methods of testing this capacity. 1. The Simple Stair Test. In this the patient is made to do a definite amount of work in a given time, pulse, blood pressure, and respiration readings being taken immediately before and immediately after exercise, and after definite intervals of rest. Such a test consisted in making the patient raise his body weight twenty feet in thirty seconds (by running up a flight of stairs). Pulse, blood pressure, and respirations should return to normal at the end of three minutes.

The results are classified thus: 1. Good reactions; pulse, blood pressure, and respirations all increase on exercise and have returned to normal at the end of three minutes' rest. 2. Fair reactions; pulse, blood pressure, and respirations increase but have not returned to normal in three minutes. 3. Bad reactions; pulse and respirations rise, blood pressure does not increase. 4. Very bad reactions; pulse and respirations increase, but blood pressure falls. This test is an amplification of one originally described by Graupner (6), and often referred to as the Graupner test.

Following Goodall, Gordon Lambert (7) used this test but his exercise standard is not defined, and he quotes four cases only. He lays little stress on readings of diastolic pressure (not referred to by Goodall) but it is interesting to note that rises in diastolic pressure after exercise were slight, and that in one case he records a fall in diastolic pressure following exercise.

Goodall's second and third tests are for cases for whom the first test would be too severe. They have not been used in this investigation.

The fourth test described by Goodall is that which he calls the progressive exercise reaction. This is carried out exactly the same way as the simple stair test, only that the work is continued until the blood pressure ceases to rise. "This is the point at which the heart is just about to dilate." It is this test, of tolerance to progressive exercise, which has been mainly used by the writer of this paper, although in the earlier series, comprising some fifty or more cases, the simple stair test (Graupner) was employed.

The degree of disability suffered by most of the patients (all had had the advantage of the return voyage to New Zealand) was not great, and the majority gave reactions of the second type pulse respirations and blood pressure (systolic) increased by

exercise, and returning to normal after varying intervals (longer than three minutes).

Accordingly the more prolonged and searching fourth test—the progressive exercise reaction—was undertaken. The actual method of carrying out this test is not given by Goodall but it is imagined that some such method of periodically sampling blood pressure and pulse changes during the course of the exercise must have been employed by that writer. So far as can be ascertained from the literature available, no other investigator has either recommended or carried out just such a series of tests.

Other tests, using the blood pressure readings for the determination of circulatory efficiency, are described by Norris (8). Many of them are involved mathematically to a degree unwarranted by the unavoidable limits of error in taking the various readings. Such are determinations of blood pressure quotient, energy index, amplitude frequency product, and use of the Strassburg formula, or Erlanger and Hooker's formula. Norris recommends most highly a test described by Crampton for the determination of vasomotor efficiency. This last test itself, and my experience of it, are described below.

At this point, and before a detailed discussion of the results obtained is undertaken, the method of sphygmomanometry used may be briefly described.

Two instruments were used, a Pachon instrument with oscillometer, and a Lauder Brunton sphygmomanometer. In both instruments the pressure is recorded on a dial by means of an anaeroid, but both were kept standardized against a Riva-Rocci sphygmomanometer, with mercury column, and were found not to vary. In all cases the readings were made by the falling pressure after overstepping the obliteration of the pulse as recommended by Olliver (9). The auscultatory method (checked against the tactile for systolic readings) was used (*vide* Olliver) (10). The point determined as diastolic pressure was that at which the loud and clear note of the third phase became suddenly muffled to pass in to the fourth phase. Occasionally this change was so gradual that no diastolic reading could be obtained. This usually happened in a vigorous subject with the arterioles well dilated and the pulse beating 140 or more a minute.

No effort was made to determine or compare the length of the various phases. Where a test required two or more readings, the cuff, which was placed level with the heart, was left on throughout the test. All readings were taken with the patient lying, unless otherwise noted. The right arm was used more often than the left, but not for any special reason.

The difference between the values for systolic and diastolic pressures measures the rise of pressure in the versel due to the pulse wave. This is referred to as the pulse pressure (Olliver) (11). The leading factors in its production are "the force and duration of the ventricular contraction and the amount of peripheral resistance" (Olliver). Pulse pressure is also an index "of the volume of blood supplied to the organs per unit of time." No apology is necessary for the stress laid on pulse pressure changes in later portions of this paper (12).

The first series of experimental work to be described is that dealing with Crampton's test of vasomotor efficiency.

In this test use is made of the fact that in rising from the recumbent to the erect posture the tendency of blood pressure to fall as a result of gravity is corrected by an increase in vasomotor tone and (or) an increase in cardiac work. A lowered vasomotor tone means a greater increase in pulse rate and *vice versa*. Pulse and blood pressure readings are taken with the subject lying, and again after standing erect. Crampton has performed this test on a great number of persons and from his observations has constructed a scale. In this he makes those cases show one hundred per cent. efficiency in whom the rise in pulse rate is 0 to 4 a minute, and rise in systolic pressure equal to 0 to 10 mm. of mercury. Variations in pulse rate and systolic pressure are plotted to indicate various percentages of the optimum efficiency. The zero efficiency is at that point where the pulse rate increases from 41 to 44 a minute and the systolic pressure fall is equivalent to 10 mm. of mercury. This is the point at which the average person is unable to maintain the erect posture. No account is taken by Crampton of diastolic pressure changes. It is pointed out by Faught (13) that in normal persons the result of change of posture from lying to standing is that systolic pressure tends to fall, diastolic pressure to rise, giving a fall in pulse pressure.

This writer has records of having carried this test seventy-five times, ten times on fit subjects (young gymnastic instructors who were taking a refresher course), the remainder on patients all complaining of symptoms suggesting more or less loss of cardiac efficiency. The results vary widely. Of the ten normal subjects (Table A) in only one case was there a fall in systolic pressure in rising to the standing position and this was so small (=3 mm. of mercury) as to be within the limits of error. Increases in diastolic pressure were from 0 to 22 mm. of mercury and decreases in pulse pressure from 0 to 20 mm. of mercury.

It is apparent that pulse pressure changes, which, as has been shown, are in a great measure an index of the rate of blood flow, bear little or no relation to vasomotor efficiency as shown by Crampton's scale.

Sixty-five tests on patients with symptoms referable to cardiovascular debility showed wide variations —Tables B and C.

TABLE B

Sixty-five Cases with Diminished Cardiovascular Efficiency

Variation in changes	*Increase*		*Decrease*
Pulse rate	+40	to	—16
Systolic pressure	+25	to	—25
Diastolic pressure	+25	to	— 5
Pulse pressure	+20	to	—40

TABLE C

Distribution of Cases Referred to in Table B

Pulse rate changes	*Number of cases*	*Average variation in systolic blood pressure*	*Average variation in pulse pressure*
—16	1	+15	+13
—12 to 0	10	+ 5.2	— 3.2
+ 1 to +12	29	— 3.4	—12.5
+13 to +24	16	+ 1.6	— 5.0
+25 to +36	8	— 6.9	—15.0
+37 to +40	1	—10.0	—18.0

The only uniformity—remarked in both fit and unfit subjects—is that diastolic pressure is higher in the standing position, and pulse pressure almost uniformly lower, although there is in general a rise in pulse rate. Put conversely, the adoption of recum-

bent position results in a rise in the pulse pressure and a lowering in pulse rate, that is, the work of the heart is lessened and the blood supply to the organs is increased. The former, i. e., lessening of cardiac work, has long been recognized as providing a rational basis for rest in bed, but the latter, i. e., diminished peripheral resistance with increased blood flow has not, as far as I am able to ascertain, been remarked upon previously.

The application of Crampton's test to individual cases has shown no clear connection between readings obtained and the observed clinical condition, nor the relative capacity to perform work as measured by other means. Of course this test is only recommended as one for determination of vasomotor efficiency, and it is not impossible that the presence of other factors may determine a poor cardiac reserve where the vasomotor tone is relatively unimpaired and vice versa.

TABLE A

TEN NORMAL SUBJECTS, FROM LYING TO STANDING

Variations in	1	2	3	4	5	6	7	8	9	10	*Average*
Pulse rate	—8	+10	+12	+12	0	+ 4	+12	+12	— 4	+18	+ 6.8
Diastolic pressure	0	+10	+10	+22	+20	+10	+15	+15	+20	+ 5	+12.5
Systolic pressure	—3	0	+10	+10	0	+ 5	+ 3	+ 5	+ 7	0	+ 3.7
Pulse pressure	—3	—10	0	—12	—20	— 5	—12	—10	—13	— 5	— 8.8
Efficiency on Crampton's scale (per cent.)	70	65	90	90	75	85	70	75	90	55	80

It may be of interest to record a few cases where the test was done soon after admission, and again some weeks later when the condition had improved sufficiently to warrant discharge (Table D).

As the patient's condition improves there is less fall in pulse pressure, but the amount of fall (both relative and absolute) is not proportional to the observed amount of improvement in the patient's condition.

Although in my hands this test has given somewhat anomalous results, I would not therefore condemn it as being of no value. It certainly gives an indication of vasomotor efficiency, and comparison of readings taken from time to time in course of treatment of a patient would probably assist in determining the progress of his condition.

The method of estimating myocardial efficiency finally adopted was that described by Goodall as the progressive exercise reaction and already referred to.

The manner of carrying out this test will now be briefly described. The unit exercise was that evolved for the earlier (Graupner) test and consisted in making the patient step up and down from a chair thirty times in sixty seconds. The chair was of a pattern in common use in the hospital wards. To step up on to the chair involved lifting the body weight through one and a half feet so that the unit exercise caused the subject to lift his body weight through forty-five feet in sixty seconds, or a little more than double the exercise (twenty feet in thirty seconds) suggested by Goodall. From the data the actual work in foot pounds could be calculated.

This work was done after the war and all cases examined were exsoldiers. Surprisingly little difficulty was found in maintaining a uniform rate of movement. Probably this was due to the fact that the rate, left, right, on to the chair, left, right, back to the floor, was that (120 to the minute) of the ordinary marching pace, although it was chosen in the first place quite by chance.

This formed the single exercise of the simple stair test, and the exercise unit of the progressive test.

The actual procedure was as follows: the subject, who had previously undergone a complete physical examination, was stripped of his coat, waistcoat, shirt, and in warm weather, singlet. He was made to lie down on a bed or couch, and readings of pulse rate and systolic and diastolic blood pressure taken. The pulse was counted by the ward sister and the blood pressure readings taken by me. All readings were immediately written down, and any apparently anomalous values checked by repeating the readings.

TABLE D

CASES TESTED FROM LYING TO STANDING, FIRST, ON ADMISSION, AND SECOND, ON DISCHARGE

Efficiency on Crampton's scale (per cent.)	45	80	60	35	25	30	65	40	20	15	25	50	15	65	100	80	40	35

Generally these happened together. A record of the time taken was noted, a physical examination of the heart made to detect abnormality of sound or rhythm, hyperesthesia of the precordia looked for, and a note made of the patient's subjective symptoms.

After three minutes' rest, lying, further readings were taken, and again after further intervals of rest, if this seemed desirable.

With a little care the rate—one minute exercise, half a minute for readings—could be maintained

No count was taken of respiration values as this was found to unduly prolong the rests during the performance of the exercise. After the readings of the subject at rest were taken, he was instructed in the method of carrying out the exercise. The time was noted, and unit exercise (thirty times) performed. The patient immediately lay down and readings were taken. This interval usually lasted thirty seconds. The exercise was immediately repeated and another reading taken. Again and again would the exercise unit be carried out until readings showed a falling systolic and pulse rate pressure, or the patient showed signs of considerable distress.

throughout, but a record was kept of the time as the exercise progressed.

A close watch was kept on the subject during exercise and a note made of any complaints. In this way was gained much useful information as to the power to perform work quite apart from a consideration of the series of the readings. Complaints of distress, giddiness, etc., were checked against the actual readings, and a fearful subject reassured that his heart was still acting soundly.

The body weight was known, the height through which it was lifted could be ascertained, and thus a measure of the work done was expressed in foot pounds. There was one error common to all readings, that the centre of gravity of the body was not actually raised through one and a half feet because the attitude of the subject when standing on the chair was somewhat crouching. All patients adopted the same attitude and the one effect of the error is that the actual work done is slightly less than that calculated.

One further fact must be noted, that the readings taken at the end of each exercise are taken so soon after lying down that they are practically valueless for the upright position. Provided that this fact is realized during consideration of the results obtained, it will not invalidate any of the conclusions drawn.

All records were taken between the hours of ten and twelve in the morning and two and four in the afternoon, not within two hours of the last meal, nor within an hour of the graduated exercise, which finished at 8:30 a. m. All patients were examined in a resting condition, so that the results are strictly comparable and not vitiated by any external factor that could be foreseen.

It is necessary to consider the reaction to exercise shown by normal subjects.

For this purpose there was available a class of young gymnastic instructors of the New Zealand Permanent Forces, who had just finished a six weeks' refresher course, and of these, by the courtesy of Captain A. W. Brocks, M. C., chief physical training instructor, a selection was made. These men were very fit and it was found practically impossible to tire them in a reasonable time at the rate of exercise chosen.

A chart was made giving the result of such an exercise. It showed that the subject was exercised continuously for thirty-seven minutes—in that time carrying out thirty unit exercises, i. e., lifting his body weight through one and a half feet thirty by thirty, nine hundred times, and performing 221,400 foot pounds of work.

Readings in this case were taken after each two unit exercises, i. e., after each sixty lifts, and unfortunately this was one of the cases where difficulty was found in taking the diastolic reading, but otherwise the graphs show certain definite characteristics of the behavior of the normal subject under the stress of exercise.

Both pulse rate and the systolic pressure rise on exercise, but systolic pressure reaches a maximum earlier in exercise than does the pulse rate. Systolic pressure tends to rise to its highest point early in the exercise and then to fall to a certain level which is maintained for the rest of the exercise. As the subject "gets into his stride" the pulse rate also reaches and maintains a certain level. Resting, both systolic pressure and pulse rate rapidly fall—systolic pressure falling markedly below its original level. This extra fall is an indication of the severity of the exercise and when met with after mild exercise it may be taken as a sign of diminished cardiac reserve (Otis) (14).

The line of diastolic pressure is not complete but shows two phenomena which were found to be typical of all tracings from normal subjects. The first is the early fall in diastolic pressure, a fall which is in some degree maintained throughout the exercise. This fall is really greater than is apparent from this and other tracings, as the readings after the first and subsequent exercise units are not compensated for the change from erect to recumbent posture. This unknown factor would, as we have already seen from a consideration of the Crampton test, cause the readings to be higher than if they were fully compensated for the change of posture.

One factor in the production of this fall is, doubtless, the diminution of peripheral resistance caused by the dilatation of the arterioles and capillaries. Possibly also the pulse wave being of greater amplitude may leave a deeper trough behind.

This observed fall is normally not great and is not always present even in persons who are known to be perfectly fit. Some normal cases showed small rises in diastolic pressure, but it is probable that if values had been corrected for change of posture, there would have been an actual fall in all cases, for in every normal subject diastolic pressure observed during exercise remained below that previously determined in the erect posture.

A second phenomenon in connection with the diastolic pressure is the postexercise rise observed. This is constantly present, and is again actually greater than that observed, for the observation was made after three or more minutes lying and a correction for posture would presuppose a decrease in diastolic pressure. The duration of this postexercise rise is variable, but it would appear to be comparatively short.

This rise is not easily accounted for. It is probably a vasomotor phenomenon, producing an increased peripheral resistance, although the systolic pressure is falling. This matter is still under investigation.

These observations do not altogether bear out the results obtained by Lowsley (15) who experimented with young athletes upon a stationary bicycle. The observer found a rise in both systolic and diastolic blood pressure. "The time when the maximum systolic pressure was reached varied from five to twenty-five minutes and the increase amounted to from ten to sixty-five m.m. with an average rise in sixteen minutes of 32.7 m.m." The rise in diastolic pressure varied between zero and forty m.m. Diastolic pressure reached its maximum either at the same time as the systolic pressure or a few minutes later.

In Lowsley's experiments the pulse rate reached its maximum later than did the systolic pressure. The average time for reaching the maximum was 35.4 minutes.

Unfortunately no details of these experiments have been available and the method of measuring and recording blood pressure is not stated. There is a certain amount of presumption that Lowsley's read-

ings of diastolic pressure were taken at the point of disappearance of all sound.

Notwithstanding these results I am satisfied that with an efficient myocardium and stable vasomotor system the typical reaction to exercise is found in a fall in diastolic pressure.

The progressive exercise was carried out on a considerable number of patients and will be known as the Type A exercise, in distinction to a limited and more standardized test which may be distinguished as Type B.

This second type will be described in order that the reaction to it of normal subjects may be considered at this stage. Type B exercise differs only from Type A in being limited to a series of eight unit exercises. It is carried out in the same way as is the former type as far as the first six exercise units (each of thirty lifts) are concerned. The seventh and eighth exercises are combined and the subject encouraged to speed up, the sixty lifts in normal cases being performed in one and a half minutes. The whole exercise takes eleven minutes. As before the readings are taken after intervals of rest.

A summary of the results obtained from nine young (average age, twenty-six years) gymnastic instructors examined at the close of a refresher course shows that the average diastolic pressure of the nine subjects was slightly below the value taken lying down before exercise, and a larger fall below the value taken standing before exercise. Table E shows the individual figures.

TABLE E

Diastolic Pressure Changes in Nine Normal Subjects. Type B. Progressive Exercise.

Case	Diastolic Pressure Resting (a) lying (b) standing	Exercise Units 1	2	3	4	5	6	Extra spurt 7 and 8	After 3 minutes lying
1	(a) 80	85	75	75	85	90	90	85	98
	(b) 100								
2	(a) 80	80	80	80	80	80	85	65	70
	(b) 90								
3	(a) 50	50	55	55	55	60	60	60	52
	(b) 70								
4	(a) 90	90	95	95	97	97	95	75	95
	(b) 100								
5	(a) 68	65	75	75	70	65	65	65	70
	(b) 90								
6	(a) 75	60	55	60	60	55	60	65	60
	(b) 85								
7	(a) 95	85	85	75	85	85	85	70	75
	(b) 100								
8	(a) 90	85	82	78	85	80	75	75	82
	(b) 105								
9	(a) 100	90	90	90	85	85	75	80	100
	(b) 115								
10	(a) 81	77	77	76	78	77	76	71	78
	(b) 96								

It has already been explained that the readings taken during exercise should be compared with the preexercise standing value rather than with the preexercise lying value, but if it be conceded that a mean of these values may be used, it will be seen that as far as the above experiments are concerned the diastolic pressure during the exercise was in one case only (plus two m.m.) above that mean.

The postexercise rise of diastolic pressure is also apparent.

The reaction to the extra spurt shows a tendency to subsequent fall in diastolic pressure with rise in systolic pressure, pulse pressure, and pulse rate. The graph of pulse rate shows an increasing rise with exercise, the nine component curves differing in no respect from the composite one. The component blood pressure curves show fluctuations not indicated on the composite curves, but the fluctuations are not of an order comparable with fluctuations to which pathological significance may be attached later.

There are at least two ways in which these methods of progressive exercise tolerance may be applied to problems of myocardial efficiency. That of most practical value is recommended by Goodall (16) and consists in exercising the patient to the limit of his tolerance. The actual work done, and the time taken, are recorded, and as the condition progresses, further exercise tests show what improvement (or decline) has occurred. The work done, recovery rate, etc., even at the first exercise, give valuable indication as to the power of the patient to perform work. A consideration of this enabled one to map out a routine of graduated exercise and rest, and vocational training suitable to the patient's powers.

In the case of many of the patients, particularly those classified D. A. H., there was a strong psychoneurotic element. It was a distinct advantage in these cases to be able to demonstrate to the patients their capacity for work, and their improvement, in terms of foot pounds.

It is a satisfactory method, and gives good results so far as estimation of the efficiency and progress of the patient are concerned. It is not necessary to analyze the particular form of the graphs obtained, and the method is as free from theoretical objection as any blood pressure method of estimating myocardial efficiency can be.

But an analysis of the form taken by the graphs is not by any means an unprofitable proceeding, and constitutes a second method of using the progressive exercise test.

Study of the accumulated data did not at first reveal any constant signs of myocardial deficiency, but on the contrary many cases, with comparatively early exhaustion, seemed to run a course not markedly departing from the normal.

However, it was remarked that patients with deficient work capacity when exercised to exhaustion gave curves of two distinct types. In the first, the point of exhaustion was marked by a definite fall in pulse rate, blood pressure remaining unaffected or falling only slightly, in proportion to pulse rate. In some cases the exercise was stopped owing to complaint of distress before either pulse or blood pressure fall were sufficiently great for differentiation. One or two more exercise units would probably have brought these cases under the same classification.

Further examination showed that all cases finally classified D. A. H., that is, cases conforming to Lewis's effort syndrome (17) were included in the first class.

All patients referring their symptoms to shell gas poisoning gave a similar reaction, and patients "run down" after septic or infective processes. Cases of functional nervous disease appear in this group.

The second group, with disproportionate fall in systolic and pulse pressure, included patients whose symptoms suggested actual organic changes in the cardiovascular system. Many are recorded to have had definite cardial enlargement (determined by palpation and x ray) traceable to a myocarditis following or accompanying an acute infection or to chronic renal or arterial disease. All cases diagnosed arteriosclerosis, most of them early cases, fell into this group.

Cases of valvular disease (mitral stenosis and mitral regurgitation) did not give results sufficiently definite to classify them. But it is now well recognized that an impaired valve does not necessarily indicate an impaired myocardium (18). It has also been pointed out that in cases of mitral stenosis the patients may suffer from D. A. H. that is concurrent with, rather than consequent on, their valvular defect (19, 20).

It is easier to observe these results than to account for them. An assertion has been made that D. A. H. is best described as a vagal exhaustion, vagasthenia (21). The tachycardia present in many of these cases is attributed to an alteration in the equilibrium between vagal and sympathetic factors in the direction of giving excess action to the sympathetic system.

A consideration of the various graphs will show that the value of the initial pulse rate bears little, if any, relation to the pulse rate changes during exercise. The highest pulse rate obtained was in a case where the pulse was uncountable and above 180. The exercise continued, and the rate fell suddenly to 144 beats a minute. There was no corresponding variation in the blood pressure readings.

The onset of exhaustion, in the first group of cases, accompanied by very real distress—giddiness, staggering, complaint of precordial pain—and a falling pulse, points to a condition of exhaustion of the sympathetic system. Two possibilities suggest themselves, a rapid exhaustion of the sympathetic apparatus, underproduction or overproduction of some undetermined internal secretion bringing about the distress, or the distress may be due to defect in the conducting mechanism of the heart (cf. Stokes-Adams syndrome). Actual heart block is not suggested as the pulse rate falls gradually, and the pulse is not intermittent.

The fact that blood pressures are maintained at the point of distress may be due to an attempt by vasoconstriction to overcome the cardiac distress. In spite of the pressure readings the pulse on palpation gave the impression of weakness. Notice that diastolic pressure rises.

The work already done leaves one but on the threshold of the subject. This much seems clear, that D. A. H. is a systemic rather than a local condition, and that one should commend attempts to devise a diagnosis which would not focus the attention of the patient (and his medical adviser), on the heart (22).

However, this paper is not directly concerned with the wide subject of D. A. H., but with the more limited one of blood pressure changes.

The behavior of the second group of cases is not difficult to understand. In the presence of definite myocardial damage it is only natural to expect to find on exhaustion a rise in pulse rate with a fall in the force of the heart beat.

These are the cases to which Goodall refers in his paper (23) as showing on exhaustion a fall in blood pressure interpreted as the point at which the heart is just beginning to dilate.

Some ten per cent. of all patients exercised showed a pulse pressure remaining throughout the exercise at a lower level than did the diastolic pressure. These were all cases of poor staying power, but all cases classified "poor" did not show this feature. Few of the cases which did show it were in the D. A. H. group. At present no generalization is possible with regard to this sign.

Nicholson (24) has pointed out that in hysteria the blood pressure readily becomes high owing to nervous stimulation of the vasomotor centre. The highest blood pressure readings in the series of cases examined were found in a case of functional nervous disease.

The usefulness of Type B exercise is not yet fully worked out. It is a standard test, and therefore results from it can more easily be compared. It takes less than twenty minutes and is therefore more convenient than a test of indefinite length. It is hoped that a study of the form of the graphs obtained may give a basis for the estimation of efficiency. The extra spurt which ends the exercise should reveal the power of the heart to respond to a call for extra work.

Investigations along these lines is proceeding, but it would appear from material already collected, that the extra spurt should be made more severe.

Remark has already been made of the psychotherapeutic value of exercise tolerance tests, but one wondered sometimes if they had any curative value also. The sense of well being that comes to a fit athlete an hour or two after a hard football match is common experience. Occasionally patients said they had this same feeling after being fully exercised and were quite certain later that a definite and lasting improvement in their condition had taken place.

This improvement was real and borne out by their increasing activity and keenness. Constant observation of these cases failed to disclose a psychoneurotic factor and in all of the cases the particular test to which value was ascribed revealed a definite lack of cardiac reserve.

Unfortunately the number of such cases was extremely small (only two or three out of some sixty or more examinations).

CONCLUSION

It only remains to add a few words in conclusion. I am well aware of the many defects in this paper. There yet remain many experiments that should be done, and before a detailed analysis of the types of graphs obtained can be undertaken much greater study of the underlying principles must be carried out.

This paper does not pretend to be more than a preliminary communication upon certain methods of tabulating blood pressure and pulse rate changes in normal and diseased subjects during exercise. The experimental work has been fitted into half hours snatched from a busy day, and in many cases a close consideration of readings was not possible until after the particular subject had passed out of reach into civilian life and the opportunity for confirming or extending the observations was gone.

Nevertheless what work has been done has been carried out with all care and the generalizations arrived at so far appear to rest on solid foundation. These may be summarized as follows:

SUMMARY

1. There is a fall in diastolic pressure in normal subjects during exercise, and a rise at the conclusion of exercise.

The postural factor in my observations has already been discussed. Of course all readings should be taken standing, but certain manipulative difficulties have so far prevented this being done satisfactorily.

2. Cases presenting the effort syndrome without objective signs of cardiac disease show on exhaustion a falling pulse rate while maintaining blood pressure levels. Exhaustion of the sympathetic nervous system is suggested by me as a possible cause of this phenomenon.

3. Patients presenting cardiac enlargement, arteriosclerosis, or other condition of unhealthy myocardium show on exhaustion a fall in systolic and pulse pressure with a pulse rate persistently rapid, or increasing. Exhaustion of the myocardium will explain these occurrences.

One is only just on the threshold of new territory and it is my intention to follow up the work already done. It still remains to be determined whether normal subjects, exercised to absolute exhaustion, would not show the same reaction; that is, do effort syndrome cases show a specific reaction to fatigue or merely a premature onset of the normal reaction?

I believe that they will be shown to give a specific reaction. The effort syndrome is a clinical entity in civilian practice and it seems worth while to investigate the matter further. The indications at present would justify a tentative description as a certain plus action (sympatheticotonia) of the sympathetic system or of certain of the substances activating, or activated by that system. On exercise there develops fairly rapidly a condition of sympathetic asthenia a weakened action of the sympathetic nervous system, due, shall we suggest to an alteration in composition, or in degree, of substances activating that system.

For the present this must remain pure theory and outside the scope of these investigations. It is enough to have demonstrated the value of the method and the promise of future knowledge which it holds out.

The author's references will appear in his reprints.

Hypertrophy of the Heart*

WILLIAM D. REID, M.D.
Boston, Mass.

It has been generally believed that hypertrophy of the heart muscle is a direct effect of increased work on the heart. In accordance with this belief the handicap of the various lesions, such as damage to the valves, was said to be compensated for by an increase in the size and power of the cardiac muscle; the conception of compensation was based on this belief. When, in spite of an increase in size of the heart muscle there were symptoms of an impaired circulation the expression "broken compensation" was applied. Physical work, when heavy and repeated, has been held to cause myocardial hypertrophy; the socalled athlete's heart was said to owe its origin to this result of physical exertion. Hypertrophy of the myocardium is a common finding at necropsy in cases of heart disease. Hypertrophy of the cardiac muscle has been considered an important departure from the normal, and clinicians have devoted much effort to its detection in the living patient.

Of late, however, doubt has been thrown upon the existence of the athlete's heart. Also many cardiologists have largely abandoned the theory of back pressure and purely mechanical conception of cardiac insufficiency; the latter is being attributed more and more to an active infection. It is being realized today that the exact reason for the development of hypertrophy of the myocardium is uncertain. In spite of the large amount of work, experimental and otherwise, that has been done on the problem of cardiac hypertrophy it is felt to be difficult to interpret the significance of the results.

This, then, is a statement of the present situation as regards the subject of hypertrophy of the heart muscle. It would seem that the matter may be considered reopened for discussion.

*From Department of Medicine, Boston University School of Medicine.

Hypertrophy of the heart muscle may be defined as a growth of the muscle beyond that which is normal for the age, sex, stature, and other conditions of the patient in whom the heart is placed. The condition presents itself in the form of either a deposition of perfectly new cells or an increase in the volume of those already present, probably mostly the latter.

Evidence has been accumulating that if the heart is fully normal it does not undergo hypertrophy as a result of athletics, even if the latter are practised over a considerable period. For example, it was found that the hearts of oarsmen (1) and of marathon runners (2) were not enlarged. The same was true of some six day bicycle riders (3), their hearts were observed to be extraordinarily quiet. The pulse rate, even when the riders had just come off the track, was not higher than 80 and most of them were in the sixties. The heart sounds were faint, but the pulses were strong.

It is well known that hypertrophy of the heart muscle is found in hearts that are affected by disease, if the latter has been present long enough to permit a hypertrophic change in the muscle. In considering the reason why this occurs one readily thinks of an increase in the blood supply and therefore of the nourishing of the myocardium. The main blood supply of the heart walls is that delivered by the coronary arteries, and the physiologists have shown that the coronary stream is directly dependent upon the pressure obtaining in the first part of the aorta from whence the coronaries have their origin. In accordance with this, in hypertensive states one commonly finds hypertrophy of the heart muscle, but on the other hand the myocardium may be hypertrophied in conditions in which an increase in the blood pressure does not occur. The problem is not, then, so

simple; let us turn for a moment to the matter of the hypertrophy of other muscles in the body.

In general it is known that the normal growth of the muscles, as well as of other tissues, is directly influenced by the age, health, and diet of the individual. Growth is a normal phenomenon in the young and gradually ceases as the period of adult life is reached. Also, there is abundant evidence that growth is much influenced by a favorable diet; a generous supply of foods of high calcium and vitamine content is important.

But with these factors of normal growth we are less concerned; the problem of this paper is that of muscular hypertrophy, which perhaps may be defined as growth beyond that normally achieved. It is a common observation that muscles hypertrophy when subjected to excessive use. Burton-Opitz states that when exercised, the skeletal muscle acquires new cells as does the uterus after its reception of the fertilized ovum. The same physiologist (4) writes: "It must be evident, therefore, that the metabolism of a muscle is absolutely dependent upon its connection with the central nervous system. For this reason, it is commonly held that the ganglion cells exert a trophic influence upon the muscle, which, however, is brought to bear upon it through its ordinary motor nerve and not through special trophic fibres. Hence, any motor nerve may be said to possess trophic qualities because it keeps the muscle in activity, thereby favoring its metabolic processes. The blood supply is, of course, of some importance, because a copious flushing out of the muscle retards the process of degeneration, while a scanty blood supply favors the occurrence of these changes."

What happens if a muscle is deprived of its nerve stimuli, as happened in many of the wounded in the recent World War? J. B. Stewart and A. Evans (5), in discussing what takes place in muscles whose nerve supply has been cut off by gunshot wounds, state, ". . . actual pathological changes take place in a paralyzed muscle. The degenerated muscle fibres become infiltrated with connective tissue cells, fibrous tissue and fat, and become converted into a fibrofatty mass, so that now, instead of contractile muscle fibres, we have more or less of this inert, non-contractile substance." It seems needless to give further references or authority for the assertion that the growth of skeletal muscles is dependent upon impulses received from the nerves.

It is suggested that hypertrophy of the heart muscle is due to stimuli from its nerve supply, probably mostly those from the sympathetic system which are augmentative in effect.

The primary purpose of the heart may be said to be that of propelling a sufficient amount of blood to the place where the latter is used, namely, the capillary field. Whenever there is not enough blood flow in the capillaries to meet the tissue needs certain automatic adjustments take place. Constriction of some vessels and dilatation of others may shunt the blood to the regions in which it is particularly needed and permit a freer flow, respectively, while certain reflex nerve stimuli may cause the heart to increase its rate or force of contraction. If this stream of reflex nerve stimulation proves frequent hypertrophy of the heart muscle results.

On this Burton Opitz (6) writes: "Hypertrophy finds its origin in the fact that the cardiac cells are in a tonic condition and react to excessive stimulation by increasing their power of contraction. This change eventually produces a compensatory increase in size and massiveness of the heart."

Some have thought that the size of the capillaries was dependent almost entirely upon local metabolites. Thus, Dale and Richards (7) have shown that histamine will cause a dilatation of the capillaries even after the nerves to these vessels have been severed. But Bayliss (8), in discussing the subject of vasodilatation, writes, ". . . although metabolites are a partial cause, there is a nervous effect in addition, since the degree of dilatation is not in proportion to the increase of oxygen consumption." And further one finds, "The effect of products of metabolism of active organs is to cause dilatation of the bloodvessels, thus ensuring an automatic regulation of blood supply. But the facts do not account for the whole of the vasodilator phenomenon met with, which require the existence of vasodilator or inhibitory nerves (9)." Although the problem is complex I believe that study of the literature of physiology warrants the assumption that when conditions in the peripheral field of the circulation are not right there are reflex stimuli to the cardioaccelerator centre in the medulla and thence to the heart, causing the latter to increase its rate or force of stroke.

The heart normally is constantly working with, of course, short intermissions of rest, i. e., diastolic periods, and yet it does not hypertrophy. The normal heart, as is well known, has so much power in excess of ordinary needs and the cooperation of the vascular elements is so perfect that there is little need for excess reflex stimulation of the heart. In persons trained to athletic pursuits the automatic dilatation of the peripheral vessels works so efficiently that here again the needs of the faster circulation may be met without much extra stimulation of the heart.

In disease the impairment of the heart itself or of the vessels in the periphery is such that the circulation in the capillaries may easily not be adequate in quantity or in quality of blood. In either case it is conceivable that a continuous stream of impulses of augmentative type and mostly through the sympathetic system may be at work upon the heart. The myocardium may then hypertrophy and the heart may or may not be able to maintain an adequate circulation.

Hypertrophy, then, may still be looked upon as evidence of abnormality, as it occurs only in response to a stream of stimuli which normally do not exist, as under normal conditions the automatic adaptations of the circulatory apparatus take care of all needs.

A little thought will show that this conception of the working of the circulation supports the abandonment of the back pressure theory as an explanation of cardiac insufficiency. For example, in hypertensive states the myocardium hypertrophies and sooner or later the heart may show evidence of inability to cope with the situation, but it must not be considered that the peripheral resistance, which is increased in hypertensive conditions, of itself caused the heightened blood pressure and subsequent myocardial hypertrophy. The increased level of the

blood pressure is, of course, due to the energy produced by the muscular contractions of the heart, and, according to the theory advocated in this paper, the hypertrophy of the heart muscle is the result of the stream of reflex nerve stimuli for augmented contractions.

The reader is warned that it is not asserted, in this paper, that nerve reflexes are the sole means by which the circulation is regulated. The effect of nerve stimuli of reflex origin is, may I repeat, believed to be the primary cause of myocardial hypertrophy.

SUMMARY AND CONCLUSIONS

Hypertrophy of the heart muscle has long been considered as satisfactorily explained by the assumption that it was due to increased work of the heart, but since evidence has accumulated that the normal heart does not hypertrophy even in trained athletes, while hypertrophic changes are commonly present in heart disease with or without increased blood pressure, it would seem that the subject is reopened for discussion.

Consideration of the physiology pertaining to the growth of skeletal muscle discloses that the latter is absolutely dependent upon the connection of the muscle with the central nervous system. Trophic influences are supplied through the motor nerves; the blood supply is of secondary importance.

It is suggested that hypertrophy of the heart muscle is due to stimuli from its nerve supply, probably mostly from the sympathetic which is augmentative in type.

The primary purpose of the heart may be said to be that of propelling a sufficient amount of blood to the place where the blood is utilized, namely to the capillary field in the periphery.

When the blood supply in the capillaries is not sufficient for the needs of the tissues certain adjustments of the circulation take place. Some of these are local in their action and in addition there are reflex nerve mechanisms back to the heart.

It is these reflex nerve stimuli to the heart which, if sufficiently repeated, are suggested as the essential cause of hypertrophy of the heart musculature.

The Classification of Murmurs with Special Reference to Extracardiac Murmurs

J. EPSTEIN, M.D.
New York

Heart murmurs may be classified into three groups: the intracardiac, the cardiac, and the extracardiac. This division is based upon their source of origin and formation. Since murmurs are the predominant signs of heart disease, their proper grouping will serve to a clearer understanding of cardiopathology and cardiotherapy.

The intracardiac group of murmurs are the result of disease of the inner part of the heart, involving the endocardium, the valves, and their associated structures. They are caused by some interference with the normal passage of the blood from chamber to chamber or from chamber to the pulmonary or systemic outlet. This interference with the proper circulation may be due either to an obstructive or to an imperfectly guarded valvular mechanism. As a result of these intracardiac changes there are formed a variety of murmurs depending upon the location of the valvular defect, the nature of the deformity, the period during the cardiac cycle, the propagation of the abnormal sound and the cardiac strength. The intracardiac murmurs are the most common and form the largest group. They all have certain general characteristic features which identify them as intracardiac murmurs. They always take their origin from a valvular area and have a definite route of transmission, with a gradual increase or decrease in intensity. They coincide with either phase of the cardiac sound, blending with it or obliterating it, and add their own musical quality and strength.

To the cardiac group of murmurs belong all those which are caused by structural abnormalities, pathological changes, or physiological disorders of the myocardium. Structural cardiac abnormalities are mainly congenital and give rise to the congenital murmurs. These murmurs are diagnosed by their presence in early life, their localization to the base of the heart, their bizzare character, and in many cases, by the associated cyanosis, clubbing of the fingers and policythemia.

Pathological changes of the myocardium, whether inflammatory or degenerative, give rise to murmurs. These murmurs are caused by an imperfect closure of some valve or by an uneven roughened outlet, associated with a weakened or sclerosed myocardial

wall. They are usually heard at the mitral or aortic region, and have a limited area of transmission. They appear distant, of even intensity, and lack in vigor and musical quality. Arrhythmia is occasionally present.

Physiological cardiac disorders frequently cause murmurs. These murmurs are not the result of disease of the myocardium but of some dysfunction of the physiological properties that control the heart. The five primary physiological functions which govern the heart are known as stimulus production, excitability, conductivity, contractility, and tonicity. It is a lack of proper tonicity which causes a murmuring of the heart. Cardiac hypotonia may be of congenital origin or caused by malnutrition, anemia, cardiac fatigue, hypoadrenia, improper nerve control, or febrile diseases. Congenital cardiac hypotonia may be due to a congenital shortening of the cardiac muscle fibres. In any given heart the greater the length of the muscle, the stronger its contraction. According to Starling (1), "Tone is proportionate to the energy per unit length of muscle contracted." An atonic relaxed heart, whether congenital or acquired, will be unduly stretched by the sudden intraventricular impact during systole and give rise to a weak contraction with an abnormal vibratory movement and a soft systolic murmur.

It is this murmur which, because its origin was imperfectly understood, has received a variety of names of which, inorganic, hemic, accidental and functional are commonly known. Since, however, the cause of this murmur can be traced to a functionally deficient cardiac tonicity, it is a true cardiac murmur. The condition may therefore be called myatonia cordis, and the murmur itself myatonic murmur. As I have stated (2), the diagnosis of this myatonic cardiac murmur rests on the fact that it frequently changes in quality and strength, appearing and disappearing with the underlying etiological factor. It is usually heard in the mitral or pulmonic region as a circumscribed soft blowing systolic sound with no evidence of heart disease and no background of a heart damaging illness.

In the extracardiac group of murmurs may be included all adventitious sounds which are produced by the pericardium in its relation to the heart, the pleuræ, the mediastinum and the pericardiosternal ligaments. The pericardium may be primarily affected as in the various forms of pericarditis or it may become diseased by extension from contiguous organs. The extracardiac murmurs are of special interest and importance as they may be present without any heart lesion or disturbed circulation. They are occasionally difficult of diagnostic interpretation because they may simulate murmurs of the intracardiac or cardiac group.

The extracardiac murmurs may be divided into pericardiocardiac, pericardiopleural, pericardiomediastinal and pericardiosternal. The pericardiocardiac murmurs or frictions are usually heard best at the base of the heart, sometimes at the left sternal border or apex, as a superficial, scraping double sound of even intensity. They keep pace with systole and diastole but are not exactly synchronous with them. The pericardiopleural sounds are the result of adhesions between the pleura and the pericardium and are heard best along the apex or left sternal region. They have a blowing quality or an irregular friction sound, uninfluenced by the cardiac cycle but affected by the respiratory movements. The pericardiomediastinal murmurs are too indefinite and uncertain to be of diagnostic value. The condition may be diagnosed by the associated symptoms and signs of mediastinitis.

The pericardiosternal murmurs are of considerable diagnostic value but have received little or no attention. The pericardium is held in place, above by its fibrous layer spreading along the great vessels, below by its attachment to the diaphragm, and in front by the superior and inferior sternopericardial ligaments. The upper one is attached to the inner surface of the manubrium sterni and the lower one to the inner surface of the xyphoid process. It is evident that in any case of adhesive pericarditis there will be an undue pulling and twisting of the pericardiosternal ligaments, thereby causing a pulling or tugging of the sternum and a vibratory murmur, specially at the yielding lower portion. A thorough examination should be made of the sternum in all cases of pericarditis, past or present, especially in children whose thorax is thin and elastic. In some cases there will be readily seen a retraction of the xiphoid process with each systole and on careful auscultation will be heard a tugging, twisting or friction murmur at the lower sternal portion. This pericardiosternal murmur may be considered as an early sign of adhesive pericarditis.

SUMMARY

The numerous scattered murmurs may be grouped into intracardiac, cardiac and extracardiac. The murmurs of each group indicate at once their source of origin, the part of the heart affected, the nature of the physical disturbance in the mass of the circulating blood, the anatomical and physiological pathology. Intracardiac murmurs have as their etiology a systemic infection, rheumatic or other bacterial. They always start at some valvular area, spread along a definite route with an uneven intensity, and musical quality. Cardiac murmurs are the result of some embryological error, physiological abnormality, focal infection or toxemia. The murmurs are of diverse kinds, congenital, myatonic or myocardial. Extracardiac murmurs may be pericardial, pleuropericardial or sternopericardial. The condition is usually due to a general infection which affects the pericardium, or to an extension from a diseased neighboring organ. The pericardial murmurs are double friction sounds heard with systole and diastole. The pleuropericardial murmurs are usually heard at the left sternal region, with inflation or deflation of the lungs. In all cases of pericardial disease the sternum should be carefully examined. If the xiphoid process is observed, a tugging may be seen or felt during cardiac systole, due to a pulling on the pericardiosternal ligament. The same condition will produce a vibratory sound or murmur at the lower sternal portion. This systolic tug and friction murmur is of considerable interest as it may be a sign of adhesive pericarditis.

Practical Therapeutics

THE TREATMENT OF HAY FEVER

A Study of 114 Cases

CHARLES A. SPIVACKE, M.D.

New York

The 114 cases of hay fever chosen for this study were treated in 1924. The patients were all residents of New York city and its suburbs. Since a complete detailed survey of this district with special reference to plants causing hay fever has never been made, the aid of a botanist was secured to determine which of the plants growing in the neighborhood could be regarded as the most important causes of this disease. Although the results of this investigation are not as complete as a detailed survey would be, they serve as a practical basis for the treatment of the patients herein discussed. The plants and trees have been classified according to their seasons of pollination.

SPRING SEASON

Red oak	White birch
White oak	Paper birch
Pin oak	Kingnut hickory
Chestnut oak	Pignut hickory
Maple	White elm

SUMMER SEASON

Timothy	Sweet vernal
Orchard grass	Red top
June grass	Blue grass

AUTUMN SEASON

Low ragweed	Giant ragweed
	Cocklebur

In this classification the plants, the pollen of which are all wind borne, are arranged in their order of importance as etiological factors in hay fever. The spring season begins about the first of April and ends about the middle of May—red oak being the most common cause of the disease during this period. The summer season begins in the middle of June and ends in the latter part of July. In this season most of the patients are sensitive to timothy. The fall season commences on August 15th and continues until the first frost, and practically all patients suffering from this type of hay fever react to both short and tall ragweed. Most of the cases studied showed multiple sensitivity and reacted to all the other pollens listed here, in various combinations. Reactions were also noted to pollens of plants which pollinate through irregular periods and could not be included in any of the three seasons. These may act as contributory causes of hay fever. The most important of these are: Plantain, from May to August; lambs quarter, from June to October; rye, during May and June; Russian thistle, from July to September.

Of the 114 patients, ninety-one suffered from late hay fever; nine from summer hay fever, while there was only one patient suffering from the spring variety alone. In addition to this, there were four whose symptoms appeared through all three seasons and nine through the last two seasons.

SYMPTOMATOLOGY

The symptoms of hay fever are prolonged sneezing spells accompanied by itching in the nose, eyes, throat, and occasionally the middle ear. The sneezing spells and the swelling of the nasal mucous membrane, by causing a serious obstruction to inspiration, result in a dryness of the mouth and throat due to continual mouth breathing. There is also a continuous discharge from the nose, which may become mucopurulent if the hay fever is complicated by a bacterial infection.

Not all patients, sensitive to pollens, present these symptoms, as there are a few who suffer from pollen asthma alone. However, this is a rather infrequent condition and only one such case was treated in this series. It is common to find cases in which the individuals suffer from hay fever and seasonal asthma simultaneously. Twenty-two such cases are included in this group here. Although both are caused by the pollen, the hay fever always precedes the asthma in its onset.

Patients sensitive to pollen often show sensitivity to other foreign proteins. In this series, in addition to hay fever, twenty-seven patients showed allergic manifestations due to foreign protein other than pollen. Of these, seventeen suffered from asthma, seven from urticaria and three from perennial hay fever.

POLLEN EXTRACTS

Before extraction, the weeds which were collected for this purpose, were stripped of their leaves and placed in pans of water. The stems were so weighted in the centre of the pan as to allow the heads to hang over the sides and shed their pollen on glazed paper. The water was changed daily and pollen was shed by the weeds for three or four days. The pollen, collected in this manner, was then sifted through a 200 mesh sieve to separate it from other parts of the plant that may have fallen with it.

The pollen extracts, used in testing and treating these patients, were prepared according to the method devised by Coca. The superiority of extracts prepared in this way has been amply demonstrated by Vander Veer (1). They are especially useful in ophthalmic reactions where extracts made by other methods have proved to be quite inefficient.

TESTS

Both ophthalmic and skin test were used in all cases, the intradermal method being used exclusively for the latter. The advantages of this method over the cutaneous has been demonstrated by Mullin (2), and by Brown (3) in several experiments. It is more positive than the scratch method. It is not dangerous from the point of view of constitutional reactions, only five of about fifteen hundred tests given in this series (a little more than one third of one per cent.) produced moderate attacks of hay fever. I have found the intradermal method to be generally more convenient and more satisfactory than the scratch method.

In testing a patient intradermally, about one or two one hundredths of a c.c. of the extract are in-

jected. If the subject is sensitive, a reaction will appear in about five to fifteen minutes. A positive reaction usually takes the form of an urticarial wheel, frequently with one or more pseudopods extending from the wheel surrounded by an area of erythema. The extract used in the first tests had a nitrogenous content of .0001 mg. nitrogen to the cubic centimeter. If the patient gave a slight or a moderate reaction to this test, further tests of stronger solutions were given until a marked positive reaction was obtained. The degree of the patient's sensitivity was determined by the size of the wheel, the area of erythema surrounding it, and the nitrogenous strength of the extract which was found necessary to obtain a marked reaction.

The ophthalmic test was performed in the usual manner, consisting of the application of one or two drops of the pollen extract, by means of a tuberculin syringe, to the conjunctiva of one eye, the other eye being used as a control. The solutions were the same as those used for the skin tests. A positive ophthalmic reaction is recognized by injection and edema in the conjunctiva. This reaction can quickly be dispelled by the application of a few drops of adrenalin. This test was not as uniform in results as the skin test, for some patients who were clinically known to be sensitive to certain pollens and reacted positively to the intradermal test, failed to show any sensitivity when given the ophthalmic test. However, to one experienced in pollen therapy, the conjunctival reaction can be very valuable as an additional indication of the degree of the subject's sensitivity.

TREATMENT

The old fashioned manner of treating all hay fever cases alike is being discarded. The notion that desensitization can be accomplished by giving a set number of injections at definite intervals is now antiquated. With the present day knowledge of this subject and the experience gained in recent years, a marked change has taken place in the treatment of this condition. Now each patient is studied individually and receives the treatment necessary for his case. This undoubtedly accounts for the generally better results obtained by men engaged in pollen therapy today.

The preseasonal treatment is obviously the most desirable, but often a neglectful patient will present himself for treatment after the onset of the season. Such cases were treated in a somewhat different manner which is discussed below under seasonal treatment.

PRESEASONAL TREATMENT

In cases where the patient presented himself early for treatment, i. e., about two months before the onset of the season, injections were given at least twice a week until the onset of the season and then about once a week, right through the season. However, this was not strictly adhered to, as it has been my experience that the greater number of injections with smaller increases in dose, and shorter time intervals, give the best results. The proper interval between injections was determined by the local reactions following them. If the reactions became unduly severe, the doses were reduced and the frequency of the injections was diminished. It is always best, though, to give as many injections as possible in the shortest possible time. This conclusion was reached in the summer of 1923, when a few patients received intensive treatment with excellent results. These patients presented themselves for treatment about a week or two before the beginning of the hay fever season. Under the circumstances it was impossible to give them more than a few injections before the onset, except at very short intervals. Therefore, they were given daily injections until the season began, when the intervals were lengthened to two days, then to five days. Treatment was continued right through the season. In the series discussed here, twelve cases were treated in this manner, and we found that there was a greater percentage of relief among them than those who had received injections over a longer period of time before the season. This is in agreement with observations made by Duke (6).

Treatment by local application was also used. This method, as an additional means of desensitization, has been recommended by Caulfield (4), MacKenzie (5), Duke (6), and others. An extract containing .0001 mg. of nitrogen to the cubic centimetre was sprayed by means of an atomizer into the nose. This nasal spray would induce violent sneezing spells in some cases, but these were generally of short duration and were relieved by an application of adrenalin chloride. We found that the results obtained by local applications in conjunction with injections amply justified its use.

The pollens chosen for desensitization were those to which the patient specifically reacted. This is a better course to follow than the use in all cases of either the most offending pollen of a group or a mixture of the most offending pollens of a group. This is in accord with observations made by Piness (7).

There was no set rule or set series of doses for all patients. One patient may have been given .00001 mg. of nitrogen as the first injection, while another may have received a .001 mg. of nitrogen, depending on the degree of his sensitivity. The increase in the doses was governed by the local reactions. If none appeared, the nitrogenous content of the injections was increased steadily in order to bring about quick desensitization. However, if a reaction did appear, the same dose was repeated at the next injection or was reduced, depending on the severity of the reaction. There was no definite quantity of nitrogen necessary to bring about desensitization. In some cases it was necessary to inject as much as 0.2 mg. of nitrogen, while in others it was found impossible to give more than .05 mg. of nitrogen because of the severe reactions produced.

SEASONAL TREATMENT

As has been said above, patients, even though they received preseasonal treatment, continued to receive injections right through the season. Local treatment, however, was discontinued at this time, as it caused great discomfort to the patients. In addition to this type of seasonal treatment, there was still another, that given to patients who presented themselves for treatment after the onset of their symptoms. Great caution was exercised in the treatment of these cases. Tests were made at first with a .00001 dilution and if no reactions were obtained, .0001 to .001 dilutions were used. The eye test, since it proved very annoy-

ing to the patient, was omitted during the season. Treatment was given daily until the symptoms were relieved, when the interval between injections was lengthened to two or three days. As in preseasonal treatment, the nitrogenous content of injections was dependent on the degree of the patient's sensitivity and the reactions as they occurred. Sixteen patients received seasonal treatment in this series.

CONSTITUTIONAL REACTIONS

In the treatment of this series of cases, several constitutional reactions occurred. In spite of cautious handling, such reactions will occur. They are unavoidable, no way being known to prevent them as yet. In the group of cases studied here, there were twelve reactions in all, six taking the form of hay fever, three hay fever and asthma, one hay fever, asthma and abdominal crises, one urticaria, and one conjunctivitis. These reactions occurred shortly after the injection and were relieved with adrenalin chloride. Local reactions, taking the form of an edema or urticaria, were much more common, in some cases occurring a few hours after the injection, but they soon disappeared with slight if any discomfort to the patient. A rather unusual sort of reaction was noted in five cases. A few hours after the patient was injected, urticaria was noticed at the site of the last previous injection, although no reaction occurred when the previous injection was given.

Patients were always kept in the office for at least half an hour after injections so that those who showed any symptoms of reactions, were immediately treated. From the results obtained in this series, it would seem that the patients who suffered from either constitutional or local reactions, were the ones who obtained the most benefit from the treatment.

RESULTS

Of the 114 patients treated, 41 or 35.9 per cent. were completely relieved of their symptoms; 46 or 40.4 per cent. received marked relief; 15 or 13.1 per cent. received about 50 per cent. relief, and 12 or 10.5 per cent. received slight or no relief whatsoever. In the group of twelve who received the intensive treatment described above, 5 or 41.7 per cent. were completely relieved; 5 or 41.7 per cent. received marked relief; one received about 50 per cent. relief, and one was only slightly relieved. Of the 16 who were treated after the onset of the season, 7 or 43.8 per cent. were either completely relieved or obtained marked relief; 6 or 37.5 per cent. received about 50 per cent. relief, and 3 or 18.7 per cent. received no relief.

CONCLUSIONS

1. In order to obtain the best results in the treatment of hay fever, a survey should be made of the flora in the local district.

2. The intradermal method of testing gives greater certainty as to results than the cutaneous method and is not more dangerous as to constitutional reactions.

3. The intensive, preseasonal method of treatment gives the best results.

4. Patients who neglect to obtain prophylactic treatment can still be relieved after the onset of their symptoms.

5. Constitutional reactions are often unavoidable and means should always be at hand to relieve them. Furthermore, it seems that those patients who have either local or constitutional reactions, obtain the most relief from the treatment.

Therapeutic Effects of Ultraviolet Radiations.—C. Lee Pattison (*Lancet*, October 18, 1924) asserts that not all the benefits obtained from heliotherapy are due to the effect of light. Some of these effects are due to the increased metabolism resulting from the associated exposure of the naked body to cool air. The rays of light emitted by various apparatus giving artificial light are shorter than the rays from the sun and may have quite a different physiological effect than the rays of the sun.

There are two ways in which the ultraviolet radiations may act beneficially: 1, by increasing the bactericidal power of the blood, and 2, by activating the vitamines in the body.

Any insult to the skin, whether produced by ultraviolet and invisible rays, or by dark heat, or by blistering agents, appears to provoke or increase the defensive power of the body. Probably the results are brought about in two different ways: 1, by the warming of the blood, due to the absorption of dark heat and the visible rays; 2, by the absorption of the products of tissue damage acting as a stimulant to immunizing mechanisms.

It has been shown that ultraviolet light activates the fat soluble A vitamine already stored in the body, although it has no power of synthesizing it, so in that respect (in calcification and growth) ultraviolet radiation applied without giving vitamine A in sufficient quantity would have no beneficial effect.

Pattison believes that the commonly accepted assertion that the degree of pigmentation is an indication of the resistance of the body to disease is wrong. It is well recognized that the complexion of the patient influences the amount of pigmentation; blondes pigment with difficulty and persons with red hair less easily still. Apart from these primary differences, there are at least three distinct types of pigmentation, which may occur irrespective of the complexion of the patient. 1, The dark reddish brown color, later almost chocolate brown, which follows exposure to the sun's rays and to radiations from the carbon lamp; 2, a slatey gray color which follows prolonged exposure to the quartz mercury vapor lamp; 3, various shades of yellow, somewhat like the color of cachectic patients. This form of pigmentation may follow the use of any source of ultraviolet light, and chiefly in patients who are not making satisfactory progress. Patients show individual variations in their pigmentation reactions to the various sources of radiations, and, apart from the yellow type mentioned above, the degree and type of pigmentation are no indication of the response to treatment.

Historical Medicine

A Parallel in Civilizations

JONATHAN WRIGHT, M.D.
Pleasantville, New York

It is curious to note how close to the thought of the modern world the thought of Plato's world is. Of course to some degree it is explicable on the theory he it was transmitted so largely that of ancient Greece to us. Yet it is not always apparent at first glance, but as one becomes aware of the implications of any special phase of it we get an insight into their parallelism. It is perceived the mental pabulum, that upon which thought feeds, the phenomena in their essence which surround us, differs but little. The process of the digestion, the sequence and the relativity of the thought, differ very much and this is what at first distracts us. But the resulting wisdom in a broad synthesis is the same. Some of its implications involve problems of medical interest and these of course I have chosen to set forth in these essays, but it is often necessary to allude to other matters in the way of emphasis and illustration. Many of the dialogues, which at one time or another, by one or another critic, have been attributed to Plato are rejected by more discriminating Platonists as spurious—many apparently being theses set in imitation of the master. Such a one is the Cleitophon in which it is insisted with great emphasis that men should have a concern not only for the way they make their money but for the way in which they disburse their wealth and for the proper bringing up of those who are to inherit it. It is the conception, become so familiar and a little irritating, which modern men of wealth declare they entertain as the trustees of the people.

Memorial to Andrea Vacca Berlinghieri by B. Thorwaldsen

After this, which to us has already become a tiresome platitude and a nauseous hypocrisy in the mouths of many, we would expect a more noble tribute to our art than the author's definition of medicine as "like all other trades, a mere common agreement as to what is useful and profitable to do." We protest that is not what it was even in the time of Hippocrates. The Hippocratic *Oath* is full of the promise of self control and attention to duty. Socrates was ever teaching the same. Sophrosyne is in the way of becoming one of our own watchwords as the heirs of Greece. We are continually going to extremes and ever returning to means, *ni quid nimis;* the first term is one of experiment and the latter of doubt. In the *Dissoi Logoi,* as I have it from Dupréel, notes supposed to have been taken from the lectures of sophists before the time of Plato, we get the same order of thought. The *Oath* of Hippocrates is the highest expression of the morality of the Socratic philosophy: "Into whatever houses I enter I will go for the benefit of the sick and I will abstain from every voluntary act of mischief and corruption." There was the abode of the women and it was hedged by the jealousy of the harem. Behind the oath lay the public demand for the assurance it vouchsafed. On this assumption of the trace in it of oriental influence we think of Cos, the island lying off the coast of Asia Minor. We do not protest indeed at the sentiment of the Cleitophon, but there can be no doubt this "was the useful and profitable thing to do," in that locality especially, and especially for the family practitioner.

This attempt on my part at the modernization of Athens in the time of Plato is apt to become a little strained and even grotesque if it is pushed too far, but I will venture upon one more example of it and it will be easy to find in all histories of ancient medicine the references to the sayings of Herodotus and of Celsus which set it forth. When Herodotus noted the splitting up of the Egyptian profession into specialties, he noted a fact in a land of great cities and a teeming population. One cannot but be surprised and think that Herodotus would surely have been astonished, if he had known that Celsus in a crowded and imperial Rome evidently noting the same thing, thinking of its eye specialists and accoucheurs, would allow his thoughts to travel back six or seven centuries and suggest that Hippocrates himself was a specialist in a way. It was he, was it not, differentiated medicine from the other sciences and made it his specialty? The *Ancient Medicine* and *The Airs, Waters and Places* prove how great he was in philosophy, but medicine was his specialty. Yet Herodotus, the contemporary of Hippocrates, would hardly have thought of the isles of Greece and its stony coast lines demanding such a specialization. The specialization of the sciences depends then not entirely on crowding populations in large cities, but on crowding thoughts as well. Specialization in practice doubtless depends on the thronging city, but specialization of thought depends on the rich-

ness of intellectual life. Civilization means something more than flourishing cities. The latter indeed may divide the practice of medicine, but there is something else at work which produces in the same age great men in medicine, great physicists, great philosophers, great dramatists, great poets, whose works bid fair to endure forever, great historians who have set models of style so different as those of Herodotus and Thucydides towards the perfection of which historians are still striving and regarding the differing merits of which they are still unconsciously quarreling.

The *Lesser Hippias* is not usually reckoned among the genuine Platonic dialogues. Both it and the Cleitophon are supposed to be productions perhaps of pupils imitating the master or of later plagiarists trying to sell wares labelled with the name of Plato. The *Lesser Hippias* is not so low in the fibre of the thought and style as entirely to warrant this criticism, it seems to me, but I am not familiar with the other arguments excluding it from the list of Plato's undoubted works. At any rate it marks the fact that in the time of Plato or shortly succeeding it, there was discussion of the pros and cons of specialization of knowledge in Athens. Like every question for Socrates it had two sides. In the *Lesser Hippias* it served his purpose for the moment to ridicule those pretending to or thinking they possessed universal knowledge. He parades Hippias in ironical fashion as an encyclopaedic person on his way to the Olympic games fully equipped with everything he had made himself. He was decked out with seal rings he had made himself, with cloak and tunic and girdle and sandals and in his traveling bag he carried a strigil and a flask with home brew (—of oil), all his own. Under his arm were poems, epic, tragic and dithyrambic. "I forget what else you said you had with you of your own manufacture, but I remember you were a memory teacher, too." Stabbing men under the fifth rib thus is what led Socrates to his doom.

There is nothing so enlightening as to the seething mentality of the epoch as this play of wit of Socrates on the problem we actively discuss today,—how to synthetize the vast ocean of facts revealed as the product of Greek genius for objective and subjective research. We owe it to Dupréel to have pointed out in his "Socratic Legend" that the *Dissoi Logoi,* the student's note book, contains jottings of such lectures delivered at some Chautauqua under the shadow of the Acropolis something like twenty-five hundred years ago. In this age of all-pervading specialism we know that at that time, on the basis of what for us would probably seem an infinitesimal number of facts there was a very marked specialization of mental activity, but there were still a few people like Hippias, game for Socrates, who pretended to know how to do everything and no doubt there were a fewer still whose personal vanity was so whetted by a realization of the many things they did well they really believed they *could* do everything. A story is told of Lord Brougham by Lord Grey of the Reform Bill apropos of his imperturbable confidence in his own ability. They were on horseback, Lord Grey in the lead, as they came to a swollen stream. Familiar with it, but when half over finding it deeper than he had expected as he approached the center of the ford, he turned in his saddle and called back: "Brougham, can you swim?"

"I never have, my lord, but I have no doubt I could if I tried."

Socrates is represented by Plato in the fifth century B. C. as ridiculing the encyclopaedic Hippias for being fitted out on his way to Olympus with everything material and immaterial made by himself he was likely to use. We find in the story of Lord Grey told on Brougham the irony, which was, by the time of the beginning of the 19th century A. D., again in the air for the encyclopaedists at the end of the 18th century. By the end of the 19th specialism was in full bloom and the protest against it is only occasionally vocal.

Experiments on Man Demonstrating the Dynamogenic Power of a Liquid Extract of Animal Testicles

M. BROWN SÉQUARD

Translated from *Archives de Physiologie,* Fifth Series, No. 1, 1889, p. 651, by L. L. Stanley, of San Quentin, California.

On the first of last June, I made a report to the Biology Society, which has been followed by many others showing the remarkable effects produced upon myself by some subcutaneous injections of a liquid obtained by grinding up in a mortar a testicle of a dog or a guineapig with the addition of a little water. I have made this experiment with the conviction that I would obtain from it a notable increase of the power of the nerve centres and especially that of the spinal cord. As will be shown immediately, the results surpassed my hopes; but I have never by word or pen expressed the idea that these injections could "repair the *irrepairable* ravages of old age." I have only said and still believe that it is perfectly possible to repair "the *repairable* ravages of old age."

I hope that all fair minded men (*de bonne foi*) after a complete study of the facts and arguments will come to coincide with my opinions.

I.

The physiological and clinical history of the testicles is full of interesting and well known facts and leaves no doubt as to the role played by these organs.

Who does not know that in regard to intelligence, morale (*moralité*), and physical powers, that those who in infancy have lost their testicles by disease or otherwise, or those in whom these organs have remained in the abdomen, in which case they do not

possess their functions, are indeed inferior to other men? They are abnormal beings (*degradés*). It cannot be doubted that the testicles give to man his noblest and most useful attributes (*utiles attributs*). Cannot it be said of a man active, intelligent, (*honnête*) physically fit, brave and strong, here is a true male? On the other hand, it is well known in men who are not ill, that a considerable variation in the degree of cerebral and medullary (spinal) (*médullaire*) power is associated with a very great variation of the testicular power: the greater the sexual activity the greater the strength of the nerve centres.

It is well known that in people afflicted with diseases of the testes, in those who overindulge sexually, and those who are given to masturbation, and especially in those who suffer from seminal losses, there is a very great diminution of their physical and mental forces. That very instructive book by Lallemand on seminal losses (*Des pertes séminales involontaires,* Paris, 1836-1842, three volumes) is full of observations in that regard.

A study of the facts shows that in these cases besides the (*fâcheux*) grievous effects which can come from irritations of the sexual organs, there are weaknesses (*des diminutions de force*) similar to those observed in eunuchs' weaknesses, which incontestably depend on those substances which they lack. Because of frequent spermatic emissions they do not contain a sufficient amount of the principles which the testicles furnish for resorption.

Facts of an entirely different order also lead to the conclusion that through absorption certain substances contained in the sperm aid in increasing the forces of the nerve centres.

Normal men (*bien organisés*) of twenty to thirty-five years of age, who for one reason or another are absolutely continent sexually and who have no seminal losses from any cause whatsoever, such as an erotic dream, are in a state of excitation accompanied by mental and physical activity. Perhaps this excitation may be morbid, but it is nevertheless very great. This condition of spermatic plethora establishes just as well the dynamogenic power of the resorbed seminal principles as does the facts relative to a spermatic impoverishment.

I have received during the past months the confidential statements of a number of men who are between forty-five and fifty-five years old. They affirm that since their sexual power is diminished somewhat, they have proved that their physical and intellectual forces have become weaker after each coitus and then gradually become stronger up until the next sexual indulgence which took place twelve to fourteen days after the first. Without causing too much fatigue, sexual intercourse, as I have said, diminished their activity but in proportion to the subsequent replenishment of the supply of sperm that activity was increased, remarkably with some.

II.

These facts and others as well have led me for some time to the thought that the weakness of old men depends in part on the gradual diminution of the activity of the testicles.

In a course given at la Faculti de medicine de Paris in 1869, I said that if it were possible to inject without changes the sperm of a vigorous animal into the veins of an old man, there would probably be obtained a notable improvement in the enfeebled forces of that individual.

Imbued with similar ideas I was led to perform in 1875 numerous experiments, some of which have given extremely interesting results. But only one of them, however, has well demonstrated the considerable influence which testicles of a young animal can have upon an old dog.

For some years I have had the idea of injecting under the skin of some old and enfeebled male animal an extract made from the testicles of young and vigorous mammals. These tests made nine months ago upon some old rabbits having well demonstrated on the one hand the harmlessness of the procedures and on the other hand the importance of its use, I decided to make upon myself some experiments which appeared to me ought to be in all respects more conclusive than those made on the animals.[1]

III.

Here are in all their important details the experiments which I have made upon myself.

I am seventy-two years old. I am in general in very good health except for rheumatism and *merycisme* (regurgitation of food). Not having taken any exercise for the past thirty years my natural vigor which had been considerable had gradually diminished and for the past ten or twelve years I have become very feeble.

On the 15th of last May with the assistance of Messieurs d'Arsonval and Hénocque I removed one testicle from a very vigorous dog of from two to three years of age after I had tied off the venous plexus. After cutting all of it, including a large part of the vas deferens, into small pieces I threw it into a mortar and added a minimal amount of water. It was then ground, with breaking up of the pieces in such a way as to bring out as much of the juice as possible. After adding more water, all the liquid obtained as well as the portions of the gland was placed in a good paper filter. Filtration took place slowly and about four and one half centimetres of light rose colored liquid, slightly transparent, was collected.

I injected under the skin of one of my legs almost a cubic centimetre of this liquid. The next day and the following day as well on May 24th, 29th, and 30th, and on June 4th, I repeated the injections. The last five were made from a liquid prepared from very vigorous guinea pigs, both young and adult. There were ten injections altogether, almost all in the legs, the others in the thigh and left arm. In all cases the proportion of liquid drawn from the testicles had never been more than a fifth of the mixture with water. Each injection was about one c.c. of the mixture. It consisted of three distinct parts, first blood, secondly the sperm and thirdly the juice of the gland. These different substances were employed together.[2]

[1]In another work I will report the different experiments which this subject led me to make and in particular those with testicular grafts.

[2]For reasons which I have given in a number of lessons in 1869 and following I considered the spermatic glands as well as the other principal glands (liver, kidneys, etc.) as endowed, apart from their power of secreting, with special influence on the blood, such as is possessed by the glands without an external secretion like the spleen, thyroid, etc. With this in mind I have made experiments with blood returning from the testicles; but the results have not been conclusive enough to be described.

In almost every case I used the Pasteur filter. Dr. Henocque is satisfied that no cell (*corps figuré*) and consequently no spermatozoa can pass a filter of this kind. The effects which I have observed are therefore not due to any spermatozoa (*animalcules du sperme*).

The liquid used was transparent and colorless. All the injections had been from the first a little more painful than those of pure water or that containing alkaloids. Within a short time varying from a few minutes to a quarter of an hour the pain left but after half or three quarters of an hour it returned and acquired very rapidly in most of the cases a very great intensity. Its violence was so great that it was almost impossible to sleep the nights which followed almost all the injections. The least period of the intensity of this pain was ten to twelve hours but it has in general, after a very general diminution, persisted for many days.

Accompanying this phenomenon an erythematous redness and sometimes venous striæ (*stries d'angioleucite*) appeared with swelling and heat in a space two to three centimètres in diameter, not at the site of the needle prick but over the part where the liquid was deposited. The pain and the inflammation were much more marked on the lower extremities than on the upper.

I have been able easily to avoid the bad effects of the injections merely by diluting to a greater degree the extract of the gland used. But I wanted to know exactly the risks of the experiment and also to obtain the maximum good results possible, and for these reasons I preferred a concentrated liquid.

I am bound to say that the very numerous experiments made on dogs and rabbits have shown the harmlessness of these injections and I believe consequently that it can be said that even if the local reactions are painful there will be no bad effects.

Before pointing out the favorable results of these tests, I pray that I may be pardoned for speaking about myself. I hope that it will be easily realized that this portrayal will not have the proper value without a knowledge of my health, my vigor and habits before these experiments and those effects obtained afterward.

My general vigor, which had been considerable, had gradually and noticeably diminished during the last ten or twelve years. Before the fifteenth of May, the day of the first injection, I was so weak that it was necessary for me to sit down after half an hour of work standing in the laboratory, I went away always exhausted after three or four hours of experimentation and sometimes after two hours.

From 1879 to 1881 and for the past two years I have lived some distance from my laboratory and had to go home about six o'clock in a carriage after a few hours passed in experimental work. I was so tired that it was necessary to go immediately to bed, after taking a very small amount of food. Frequently in the past ten years the fatigue was so great after the laboratory work that I could not go to sleep for a very long time, although, prone to slumber, I arose excessively tired, having slept only a very little.

The day following the first injection and more so on the days following (five injections were made in three days, May 15th, 16th, and 17th) a radical change took place in me and I have the most sufficient reasons for saying that by the first of June, I had regained at least all the strength which I had possessed for a number of years past.

A considerable amount of work in the laboratory scarcely tires me. To the great astonishment of my two principal assistants and to others I became able to experiment for many hours standing erect and not feeling any necessity for sitting down.

Moreover, on one day, May 23d, after standing for three and a quarter hours doing very fatiguing experimental work I went home so little tired that I was able after dinner to begin a work, for publication, or a résumé of some very difficult problems. It had been twenty years since I had ceased to be capable of doing so much.[3]

(*To be concluded*)

Samson's Hair.—Every one knows the old saying, *Vir pilosus seu fortis, seu libidinosus.* The ancients believed that there was a direct connection between abundance of length of hair, moral force, physical strength and a leaning toward the delights of love. The biblical story of Samson overthrowing the Temple of Baal, massacring the Philistines, symbolizes the prodigious physical power of man heavily hirsute. We know how Delilah, with whom he was smitten*, succeeded, for eleven hundred pieces of silver, in delivering him over to the Philistines; she put him to sleep on her knee, called a barber and had him cut off Samson's seven braids of hair. Thus the Hebrews believed that the great strength of Samson resided in his hair, and that this only needed to be cut off to deprive him of his superhuman force and render him powerless. Analogous beliefs are to be found everywhere in all ages. Sir George Frazer reminds us in chapters of his *Folklore in the Old Testament* that "stories similar to that of Samson and Delilah are frequent in the legendary history of ancient Greece. It was said that Nisus, king of Megaridus, had on his head purple or golden hair and that he was ordained to die on the day when this hair should be torn away. When Megara was besieged by the Cretans, Scylla, his daughter, fell in love with Minos, king of the Cretans, and tore the fateful hair from her father's head. He died. According to another tale, it was not the life but the strength of Nisus that resided in his hair of gold; when he was deprived of it, Nisus became feeble and was slain by Minos. Thus the aborigines of the Island of Amboine thought that their strength lay in their hair and abandoned them if their tresses were cut. A criminal being examined by the Dutch denied his offense up to the moment when they cut off his hair; then confessed at once. In Europe there was a belief that the evil influence of sorcerers resided in their hair and that nothing was able to make the least impression upon these miscreants as long as they kept it. Also in France there was a custom of shaving the whole body of those accused of sorcery before delivering them over to the headsman."
—Translated from *Æsculape*.

[3] My friends know that for thirty or forty years work after dinner was impossible and I had the habit of retiring about half past seven or eight o'clock and doing in the forenoon only three or four hours work. After my first injection I was able to do very ponderous intellectual work for two, three and even one time four hours after my dinner.

Editorial Articles

THE CAUSE OF CANCER

As announced in the *Lancet,* July 18th, Dr. W. E. Gye and Mr. J. E. Barnard, F.R.S., have made some investigations into the cause of malignant growths which promise to reveal the cause of cancer, or rather the activating cause. Dr. Gye is careful to state that several factors are necessary for the production of the disease. With the aid of Mr. Barnard, who it appears has so modified the microscope that by its use viruses which hitherto have been invisible can now be observed, Dr. Gye has isolated a virus. At any rate, by the employment of such a microscope Mr. Barnard has studied the cancer virus cultured by Dr. Gye and has not only succeeded in rendering the virus visible but even in photographing it.

As pointed out in a brief editorial in our last issue the investigations carried out under the auspices of the British Institute of Medical Research were based upon or rather a continuation of researches initiated and carried to a certain stage by Dr. Peyton Rous of the Rockefeller Institute. The conclusions reached or perhaps led up to by the British investigators are somewhat as follows: Malignant new growths contain an extremely minute virus, or group of viruses, which can be cultivated. It is believed that the virus resides probably within the cells of the neoplasm. It is interesting to know that the viruses of the carcinomata and sarcomata of fowl, mice, rats, dogs and man can be cultivated. Evidence afforded by the researches of Dr. Gye and his co-workers show that the tumors produced in their experiments have a common factor, the virus, and a specific factor peculiar to every tumor, the accessory chemical substance which has manifested such startling properties. As far as is known at present one factor is impotent for evil without the active cooperation of the other factor, and the question is how does this accessory chemical substance or intrinsic cause of cancer originate in the body?

As a matter of fact there are numerous gaps in the presentation of Dr. Gye's argument which must be filled up ere the case is complete and conclusive. It is more than likely that his researches have carried him considerably further, and that many, if not most of them are filled up already. In the clearly conceived and written editorial on the subject published in the issue of the *Lancet* referred to above, a full explanation is given of why Dr. Gye's observations may be perhaps accepted as a solution of the cancer problem and an instructive sketch is made of the ups and downs of the "germ theory" of cancer. The point, however, that even in the light of Dr. Gye's work it would be foolish to state that the presence of an organism by itself can wholly account for cancer, must be apprehended in its entire significance. It seems that a correct exposition of the cancer situation at the present time is to say that cancer cannot be explained by postulating an entirely extrinsic origin. It is satisfactory to know that the line of investigation pursued by Dr. Gye and colleagues was suggested, indeed established, by an American worker and that American investigators have been well in the foreground in the attempts to solve the cancer problem.

Dr. W. B. Coley, the New York surgeon, has been ever a firm believer in the microbic origin of cancer and in a symposium on cancer at the Clinical Congress of the American College of Surgeons held in New York, October 20-26, 1924, recapitulated his faith in the parasitic theory, and suggested that the cancer parasite postulated by him required cataphylaxis to attack the cells so as to produce the cancer lesion. He urged and it now appears quite rightly that the theory of a microbic cause of cancer should not be regarded as a closed chapter. Put into plain language, it may be stated that the parasitic origin of cancer has been upheld by the result of the investigations of Dr. Gye and Mr. Barnard. It appears that there is a cancer germ but there is also a "growth factor" the "specific factor" of Gye, in the absence of which the germ is harmless, and it is upon this substance that attention will be chiefly concentrated.

In connection with Dr. Gye's discoveries Dr. James Young, of Edinburgh, speaking at the Royal Sanitary Institute Congress in Edinburgh on July 22d, said that he first described in 1921 a microbe which he was led to look upon as a cancer parasite. Since then he had found this microbe in cancers of all kinds, and was convinced it was in truth the cancer parasite. He thought it probable that Dr. Gye's ultramicroscopic virus was identical with his own and was one phase of the cancer parasite. If his views were correct the cancer parasite belonged to the most familiar and the universally distributed types of bacteria. He had consistently pointed to the necessary existence of another factor wholly different from, though linked up with, the microbe in the production of cancer. Dr. Gye's work, he said, marked a step forward in their understanding of this accessory factor, for it apparently showed that it could be isolated and stored in the test tube. This was a discovery as unexpected as it was important

and would carry them far in their experimental attempts to probe the phenomena underlying the genesis of cancer.

In an address published in the London *Times,* July 23d, which was said to have been given by Dr. Gye before the Section of Pathology and Bacteriology of the British Medical Association on July 22d on the filter passing viruses, he is reported to have expressed the opinion that the tiny "filter passing" viruses act on the body cells in a manner different from that of the larger microbes. The probability was that they actually entered the body cells and dwelt within them. They could not be stained. They were not merely phases in the life history of larger organisms. On the contrary, "the doctrine of fixity of form" seemed to hold good for them as for larger organisms.

As stated previously, it is almost certain that there remains yet much to be published with regard to the British Institute of Medical Research's investigations and that Dr. Gye, Mr. Barnard and colleagues are unwilling to make public any more results and premises therefrom until they have convinced themselves that they are founded on a sound basis. But if, as Dr. Francis Carter Wood said in an article in the New York *Times,* July 19th, if Dr. Gye has found out a germ which gives the cancer cell the impulse to grow then the use of a serum would only be in prevention not in treatment. The possibility of such prevention is very great, should Dr. Gye's work prove generally applicable to all types of human cancer. In any event, a long step in advance has been made, and as Dr. Wood says, "another brick has been placed in the foundation of the great edifice of our beginning knowledge of cancer."

While extravagant hopes are to be deprecated, further news from Dr. Gye and colleagues will be awaited with the anticipation that the first account is but an instalment and that subsequent accounts will trace the history of the researches to a more definite issue.

It may be added that the distinctive feature of the British researches is that they seem to hold out a means of prevention and not of cure. The cancer virus in itself appears to be harmless. It only becomes menacing when the accessory chemical substance is present and when the resisting powers of the system have been broken down or lowered by the introduction of degenerated tissue. If it be proved by further investigations that carcinoma as well as sarcoma are due to these causes, it also seems to demonstrate that the only certain methods of conquering cancer lie in preventing cancer, preventing the body from providing a favorable soil in which it may be harbored and wreak its harmful effects under the most favorable circumstances.

THE SURGICAL COMPLICATIONS OF TYPHUS AND RECURRENT FEVERS

Dr. Jean Rudelle, who was in the French Army in Roumania during the fearful epidemic of typhus and recurrent fever of 1916-1917, has recently published a complete memoire (*Thesis,* Paris) on the surgical complications of these infections. The complications arising in each need not be separated, because typhus and recurrent fever may occur together or successively in the same subject, the louse being the etiological factor common to each. Also the surgical complications of typhus and recurrent fever are often practically identical, hence it is difficult to attribute them with certainty to one or the other when a precise history of the case is unattainable.

In recurrent fever only suppurating processes, offering special characters and variable localizations, are encountered, involving the cellular tissue, lymph nodes, bones, joints and organs of sense.

In typhus suppurating processes are also met with although their characters are somewhat peculiar. But what is especially interesting is that arteritis of the large vessels of the limbs or arteries of the external genital organs, resulting in gangrene, is specially prone to occur.

The infectious complications of both typhus and recurrent fever are due to secondary infection from the common bacteria of suppuration. The arteritides are due to the action of the toxins on the arterial coats, ending in thrombosis. Histological examination of the vessel shows that this arteritis in no way differs from the same process arising in other infectious diseases.

The complications in recurrent fever develop after one or several attacks, while in typhus they occur after the twelfth day of the disease, more frequently during convalescence or even later. The suppuration in recurrent fever is torpid, the pus is thin, fluid, containing necrotic tissue. Cicatrization is abnormally slow. Gangrenous abscesses may develop.

The suppuration of typhus is also torpid in most cases but the pus is thicker with a tendency to extend in depth rather than in surface, while gangrene is more common than in recurrent fever and is of the dry type; exceptionally it is moist, and is then much more serious. The lower limbs and genital organs are the favorite site, the upper limbs being rarely involved. Some of the gangrene cases are very difficult to differentiate from extensive freezing followed by mortification.

The prognosis of these surgical complications is serious and increases the death rate of typhus. Several of them are in themselves serious, but many are only so because they develop in debilitated or cachetic subjects, unable to withstand the slightest surgical

interference. General anesthesia is especially serious in these circumstances.

The foci of suppuration should be opened with very small incisions, excepting gangrenous phlegmons which require free incision and excision of the necrobiotic tissue. Dakin's fluid gives excellent results.

Dry gangrene of the limbs should be dealt with surgically only when the phase of elimination is reached with a distinct line of demarcation. Rudelle advises interference in two stages, the first being division of the structures at the level of the line of demarcation in order to separate the gangrenous portion from the living structures. Two or three weeks later, when the divided tissues are a healthy red, a flap amputation or an appropriate autoplastic amputation is carried out.

Moist gangrene must be dealt with without any delay by amputation high above the upper limits of the process, or disarticulation may be done. The parts should never be sutured. General narcosis with ethyl chloride gave excellent results. Chloroform especially should never be used.

ROTATION IN SPECIALISM

Time was when a physician or a public health officer might be a specialist in many lines. A hundred years ago such men as Nathan Smith taught everything from chemistry to obstetrics and did it well, and it has not been a generation since the professor of chemistry in a leading medical school was also the professor of hygiene and sanitation. Nowadays it is difficult indeed for the most comprehensive mind to be a specialist in more than one field. However, in the U. S. Public Health Service, through force of government inertia, a surgeon in charge is still presumably capable of grasping all the details of any branch of public health work from hookworm investigation to quarantine, plan and direct such work at first glance and then be ready in a quadrennium to proceed to some other specialty, not even of his own choice, and be as superbly efficient and sufficient in his new calling for the next four years. This is akin to serving as specialists in ophthalmology, otology, pediatrics, orthopedics, and other fields for periods of four years each and, besides, to direct successfully the work of other workers under his charge in these lines. The director of research in industrial hygiene becomes in forty-eight months a director of cancer research or is shifted to the superintendency of a marine hospital.

That public health officers can adapt themselves to these changes so well as they do signifies much, but that they could do better work if their training and their aptitudes were consulted and they were not so shifted, goes without saying. Certainly nothing like it would be thought of for employees in the Department of Agriculture, in the Treasury, or in the Bureau of Standards.

The four year cycle suggests that, in its origin, this moving about from pillar to post was connected with the presidential overturn. When it originated it probably mattered little from a professional or from an economic viewpoint, but there is every reason today why the public health servant should be placed in that kind of work for which he is especially trained and adapted and kept there. This is now the case with public health officers who are not members of the regular corps who work under those of the regular service.

THE DIAGNOSIS OF OXALEMIA

Foremost among the symptoms of oxalemia should be placed the minor signs which are the forerunners of established intoxication. Among them should be mentioned a state of digestive distress although without any real pain, a torpid liver, constipation, dysuria, pollakiuria and urethral irritation; headache, migraine, and muscular and bone pain.

Among the major signs some are evident while others must be sought for until their character becomes progressively accentuated. Loeper and Tonnet enumerate the following characteristics: nausea, mucorrheic state of the intestine, with spasm, solar paroxysms, fatigue and nervous depression even reaching psychasthenia, defective memory and high blood pressure. Then albuminuria, leucocyturia and hematuria supervene, the latter contrary to the hematuria of tuberculosis being afebrile, while in cancer of the urinary tract the amount of blood lost is greater than in oxalemia.

One must also take into account the true accidents of the process, viz., a discrete or intense rheumatism localized in the limbs or around the large joints—perhaps in the form of Heberden's nodes and certain deformities. Also intestinal lithiasis in the form of small, fine, sandy calculi, grayish yellow in color and containing sometimes as much as twenty-five per cent. calcium oxalate. Renal lithiasis may be another symptom, as well as duodenal ulcers giving rise to hemorrhage, often considerable in amount.

All these symptoms may group themselves differently hence giving rise to distinct clinical forms of oxalemia.

Oxalic acid may be searched for in the urine by the technics of Neubauer, Salkowski, Lecoeur or Albahary, but the Loeper-Béchamp technic is more precise as by it one centigram of oxalic acid can be detected.

The dose of oxalic acid in the blood is absolutely

essential because an oxaluria is not sufficient to reveal the extent of oxalic intoxication. The ratio existing between the oxalemia and oxaluria is to be ascertained, because in the normal state the quantitative relation between the two is equivalent. Retention of the acid exists in a large number of cases complicated by severe abdominal paroxysms of pain, rheumatism or calculi.

Oxalic acid is also eliminated in the feces and the dosage of the acid contained in the stools is clinically useful, but the results are questionable in practice.

It is likewise interesting to search for oxalic acid in the cerebrospinal fluid, in the blood in gastric hemorrhage and renal or intestinal sand voided. Its research in the fluid derived from vesication is onlv of value in very marked oxalemia.

THE CHANGING VIEWPOINT OF PUBLIC HEALTH

It used to be the custom, and unfortunately the practice still obtains among those who are pushing health movements, to bombard the community with a rapid fire of reasons why it should desire the initiation of health work and the dire results which would inevitably follow if they did not. Health workers who are thinking about the matter are beginning to realize that this is an expensive and illogical method of approaching the taxpayer and that the ideal method is to create in the public mind a genuine thirst for health protection and better still for health development. Those who are wise in their public health propaganda are beginning to understand that the aim is not to foist something onto the general public which it does not want, but so skilfully to place the emphasis on the desirability of health that the public, which after all is a very canny animal, will have an intelligent appreciation of the quality of health. It is a good plan for health workers to depend upon this rather than upon the personality of the health propagandist, because it credits the community with a mind and a will of its own.

Health work is gradually shifting so that the people are no longer content to be merely protected against the communicable diseases or kept free of sanitary nuisances, people now begin to realize that there is something more than mere passive health and everywhere they are clamoring for those things which will keep them in a state of boundingly efficient reaction to their environment.

The medical profession should acquire this point of view. Heretofore it has placed too much stress on public pathology and too little on public physiology. In their contact with patients there is a great deal which the medical profession should do to promote genuinely active healthfulness. It is looked to as the teacher and in this teaching it should stress the desirability of an actively functioning health as against a passive freedom from disease.

CAUSES OF INFANT DEATHS

A report on the study of the circumstances surrounding the deaths of twenty-three thousand children aged less than one year in eight American cities has recently been issued by the Children's Bureau of the United States Department of Labor. One of the most significant features of this report is that it reveals a direct relationship between the earnings of the father and the life chances of the infant. The report states that "The infant mortality rates from all causes and from each principal cause of death were highest when the father's earnings were low, and lowest when the father's earnings were relatively high. When allowance was made for the variations in the size of the family, the same close correspondence was found between the infant mortality rate and economic pressure as measured by the per capita income from the father's earnings."

Another large contributing factor was found to be congestion in the home. The infant death rate of families living in houses with two or more persons to a room is two and a half times that of those averaging less than one person to a room. Mothers working during pregnancy and during the first year of the child's life have children with less, much less, chance of a life than mothers who do not. When first born infants were excluded, it was found that the mortality rate tended to increase with order of birth, that is, the larger the family the less chance for each succeeding infant to live. Death rates were found to be high also among babies who came in quick succession. A four year interval appeared to be the safest. The month of June shows the highest mortality for children born in it, because they are exposed to an increased danger of gastric diseases of summer time. August is the best month to be born in, and usually boys have a higher death rate than girls.

Obituary.

JOHN ADDISON FORDYCE, M.D.

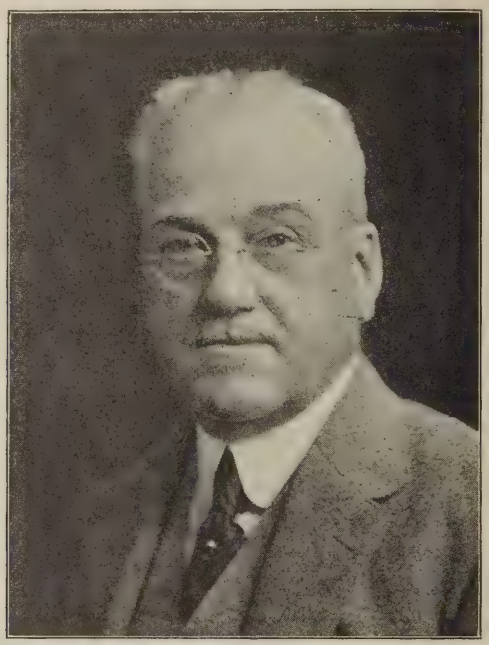
New York

John Addison Fordyce, the well known dermatologist and syphilologist, died on June 4, 1925, at his home in New York city. In his untimely demise, the medical profession has lost one of its best known and ablest members, an indefatigable worker and a keen student.

In the field of dermatology and syphilology, which Dr. Fordyce chose as his special work early in his professional career, he stood foremost among the leaders, and his work exercised considerable influence in establishing dermatology and syphilology on a firmly fixed basis.

Dr. Fordyce was born in 1858 in Guernsey County, Ohio, of Scottish ancestry. He was educated at

Adrian College, Michigan (A.B., 1878, Ph.D., 1901), and was graduated in medicine from the Medical Department of Northwestern University in 1881. After an internship in Cook County Hospital, and a brief period of general practice in Hot Springs,



JOHN A. FORDYCE, M.D.

Arkansas, he devoted several years to the study of his specialty in a number of European clinics. In 1888 he received the degree of M.D. from the University of Berlin.

Returning to the United States, he established himself in New York and rose rapidly in his profession. In 1893 he became professor of dermatology at the Bellevue Hospital Medical College and in 1912 he was appointed head of the same department in the College of Physicians and Surgeons, Columbia University, which position he held up to the time of his death.

Because of his friendship with Paul Ehrlich, Dr. Fordyce was among the first in this country to receive a sample supply of 606 for clinical trial, and he steadily remained a strong advocate of the salvarsan method of treating syphilis.

While the medical writings of Dr. Fordyce were not voluminous, they were considerable in number, particularly since the introduction of the arsenicals in the therapy and the Wassermann reaction in the diagnosis of syphilis. His literary work always bore the stamp of authority and carried conviction at all times. Among his European confrères he was highly regarded, both professionally and personally, and they were pleased to accord to him the honor of corresponding membership in a number of European medical organizations.

Those who had the pleasure of coming into personal contact with Dr. Fordyce, found him not only a great physician but a splendid gentleman, urbane, courteous and ever ready with a cordial yet restrained greeting. His place in the medical life of the great metropolis will be hard to fill. He is survived by his widow and two children.

ALBERT JOHN OCHSNER, B.Sc., M.D., LL.D., F.R.M.S., F.R.C.S. (Ire.), Hon.

Chicago

Ochsner is gone. His passing was so rapid, so unexpected. On Tuesday morning, July 21st, he was seized with an attack of coronary thrombosis, and at early dawn on Saturday, July 25th, he passed away. One week after his first evidence of illness he was laid to rest beneath the pine trees in the little churchyard cemetery of his ancestors at Honey Creek, Wis.

The world has lost a great man, a lovable character, an accomplished and industrious surgeon. Few have striven harder in the pursuit of their lifework than Albert Ochsner. Few lives have been more devoted to the welfare of mankind and of him it may well be said that he gave his life to his calling. He will be missed. His vacant chair at surgical congresses will be difficult to fill; but his name and works will not be forgotten.

Dr. Ochsner was born in Baraboo, Wis., on April 3, 1858, the son of Henry and Judith (Hottinger) Ochsner. He received the degree of B. Sc. from the University of Wisconsin in 1884, the degree of LL.D. in 1909, and M.D. from Rush Medical College in 1886. He was an intern in the Presbyterian Hospital 1886-1887, and took postgraduate courses at the Universities of Vienna and Berlin in 1887-1888. He married Marion H. Mitchell, of Chicago, on April 3, 1888.

He practised medicine in Chicago from 1889-1925, was instructor in surgery at Rush Medical College, 1889-1895; professor of clinical surgery, University of Illinois, College of Medicine, 1900-1925; chief

A. J. OCHSNER, M.D.

surgeon, Augustana Hospital, 1891-1925; and St. Mary's Hospital, 1896-1925. He spent two weeks of every three months at various surgical clinics in the United States, 1895-1907. He was a first lieutenant in the United States Medical Reserve Corps,

1908-1916, and a major in 1916. He was on active duty during the late war.

He was president of the Clinical Congress of Surgeons of North America, 1910-1912; founder of the American College of Surgeons, regent and treasurer, 1913-1925, president 1923-1924; fellow, American Surgical Association (president, 1924); member, Southern Surgical and Gynecological Society, American Medical Association (chairman, Surgical Section, 1901), Illinois State Medical Society, Chicago Medical Society, Chicago Pathological Society, Chicago Surgical Society, International Society of Surgeons; fellow, Royal Microscopical Society of England; honorary fellow, Royal College of Surgeons in Ireland; honorary member, National Academy of Medicine of Mexico, National Surgical Society of the Republic of Switzerland, and Medical Society of Stockholm; member of the editorial staff, *Surgery, Gynecology and Obstetrics.*

He was the author of numerous books, among them being *Handbook on Appendicitis* (first edition 1902, second edition 1906); *Clinical Surgery for the Instruction of Practitioners and Students* (first edition 1902, second edition 1905, third edition 1912); *Thyroid and Parathyroid Glands,* 1910; *Yearbook on Surgery,* 1917-1925; *Surgery of the Thyroid Gland; Treatise on Surgical Diagnosis and Treatment,* 1918; *Organization, Management, and Construction of Hospitals* (first edition 1907, second edition 1913), and many monographs on surgical subjects.

News Items.

Industrial Hygiene.—A plan for the protection of the health of workers in small industrial plants is being developed by the Philadelphia Health Council, under the direction of Dr. William J. McConnell, formerly of the U. S. Bureau of Mines, Pittsburgh.

Health Officers to Meet.—The Pacific Coast Conference of Health Officials will hold a meeting at Long Beach, California, September 28th to October 3d, and the annual meeting of California health officers will be held at the same place and time.

Wisconsin Medical Education.—The University of Wisconsin is now prepared to offer a four year medical course, leading to the degree of M.D. Heretofore only two years were given. The new Wisconsin State Hospital at Madison will furnish the necessary clinical facilities.

Heart Disease Mortality.—Figures for the last twenty years in Illinois show the death rate from heart disease increasing from 90 to 176 in hundred thousand of population; the disease now ranking first instead of third as a cause of death. The increase is tabulated at 145 per cent.

Wilmer Eye Institute.—Dr. Cecil H. Bagley of Johns Hopkins Hospital has been selected as first assistant of Dr. William H. Wilmer, of the new Wilmer Eye Institute of Baltimore. Dr. Jonas Stein Friedenwald of Johns Hopkins is to conduct researches in the cause and development of eye diseases.

Child Guidance Clinic.—A child guidance clinic, to be conducted for two years and financed by the National Committee for Child Hygiene, has been opened at the Children's Hospital, Philadelphia. Dr. Frederick H. Allen, resident psychiatrist at the Phipps Institute Clinic, has been appointed director, and Dr. Christina M. Leonard is chief of staff.

Researches in Gallbladder Visualization.—A series of experiments in gallbladder visualization of infancy with the aid of tetraidophenolphthalein sodium are being carried on at the Infantorium of the Heckscher Foundation, New York. The experiments are being conducted by Dr. Louis Fischer, in association with Dr. Max Einhorn; x ray studies will be made by Dr. Charles Gottlieb.

Federal Trachoma Work.—The U. S. Public Health Service has moved its headquarters for the conduct of trachoma eradication from Louisville, Kentucky, to Rolla, Missouri. Surgeon Paul D. Mossman continues in charge of the work.

Medical Library.—The library of the College of Physicians and Surgeons, New York, and the Janeway Library of the Presbyterian Hospital, will be consolidated in the new medical centre; the library will occupy the whole north front of the main building, above the entrance, and will provide a main reading room with space for one hundred and fifty students, alcoves for those doing medical research, book stacks and special study rooms, and also a faculty reading room for one hundred doctors.

Tetraethyl Gasoline Investigation.—Dr. J. F. Leake, of the U. S. Public Health Service, has been detailed to take charge of the Service's part of the investigations into dangers in the use of tetraethyl gasoline. Studies will be conducted in a middle Western city where this gasoline has been in use for several years and similar studies made in an Eastern city. Experimental garages will be maintained. Clinical and chemical studies will be made of the workers. The Service expects to present its findings in October.

American Academy of Physiotherapy.—For the next meeting of this association, to be held in Boston, October 15th to 17th, the following tentative programme is announced:

Electrophysics, by Prof. Duane of Harvard; Treatment of Sprains, by Dr. Charles P. Hutchins; The Curative Workshop, by Dr. Fred H. Albee; Electrosurgery, by Drs. Wm. D. McFee, Wm. L. Clark and Grant E. Ward; Galvanism in Neurology, by Dr. James MacPhee; the Aftercare of Fractures, by Dr. Harry Eaton Stewart; Hydrotherapy, by Dr. Robert E. Peck; Taking things for Granted, by Dr. Burton B. Grover; Intestinal Stasis and Toxemia, by Dr. William Seaman Bainbridge and Sir William Arbuthnot Lane, Bart; Application of Clear Quartz to Physiotherapy, by Dr. Berry; Indications for the Use of X ray in the Treatment of Breast Tumors, by Dr. Walter C. Barker; Some Reason for the Delay of the Correlation of Physiotherapy with General Medicine and Surgery and the Specialties, by Dr. Charles F. Stokes; The Rationale of Fraction X radiation Therapy, by Dr. J. Douglas Morgan, etc.

Clinical demonstrations in physiotherapeutic technic including electrosurgery, will be given in the Boston City Hospital.

Personal.—Dr. Chevalier Jackson of Philadelphia has been made a member of the Legion of Honor. Doctor Jackson is now in France lecturing at the University of Paris.

Dr. Allen K. Krause, of Johns Hopkins University will give a series of lectures in Chicago under the auspices of the Chicago Tuberculosis Association, beginning October first.

Dr. S. S. Goldwater, of Mount Sinai Hospital, New York, has been selected as consultant in the building of the new Syracuse Memorial Hospital, Syracuse, New York.

Dr. Herman Goodman has removed his office to 18 East Eighty-ninth Street, New York.

Dr. Louis Faugères Bishop of New York will have associated with him after September first, his son, Dr. Louis Faugères Bishop, Jr.

Dr. Shirley W. Wynne, of New York, has been appointed director of the bureau of hospitals, Department of Health of the City of New York.

Dr. Harold W. Wright has been appointed field psychiatrist to the bureau of mental health of the Pennsylvania State Department of Welfare. Doctor Wright is at present consultant to the U. S. Veterans' Bureau, in San Francisco

Dr. Horace Packard, for many years professor of surgery at the Boston University School of Medicine, has retired from active practice, in his seventieth year.

Dr. Watson S. Rankin, secretary of the state board of health of North Carolina, has resigned, and Dr. George M Cooper, assistant secretary, is in charge pending an election. Doctor Rankin took up his duties with the Duke Foundation the first of June.

Dr. George W. Goler, who has been health officer of Rochester, New York, for twenty-five years, received the honorary degree of doctor of science from the University of Rochester.

Miss Adelaide Nutting, professor of nursing at Teachers College, Columbia, for eighteen years, has retired.

Dr. Harry R. Litchfield, M.D., of Brooklyn, New York, is studying abroad during the summer.

Book Reviews

HEART DISEASE

Clinical Features of Heart Disease. An Interpretation of the Mechanics of Diagnosis for Practitioners. By Leroy Crummer, M.D. Introduction by Emanuel Libman, M.D. New York: Paul B. Hoeber, Inc., 1925. Pp. 353.

The book, as its name indicates, attempts a presentation of the essentially clinical features of heart disease. It contains many valuable facts and suggestions, but these are not always as clearly coordinated as might be desirable. The chapter on cardiovascular renal disease is rather unsatisfactory, although the author properly emphasizes the variability of blood pressure readings and the futility of all the socalled specific methods of therapy. Most cardiologists will not agree with Dr. Crummer that aortic insufficiency is frequently due to pneumococcus infection or that auricular fibrillation is quite unknown in aortic insufficiency. The concept that angina pectoris is a symptom of failure of the reserve power of the aorta is not very satisfying. Indeed, the phrase "reserve power of the aorta" leaves much to the imagination.

The author's style is fluent and the book is attractively printed and bound. It would be considerably improved, however, by a rigorous blue pencilling of unimportant material. The chief value of Dr. Crummer's work lies in the fact that it is a logical clinical presentation, written from the fundamental physiological and pathological viewpoint.

CARDIAC IRREGULARITIES

The Heart Rhythms. By Paul Dudley Lamson, M.D., Baltimore: Williams and Wilkins Company, 1921.

It is the purpose of this book to give a simple, but physiologically correct account of the normal and abnormal heart rhythms. This has been admirably achieved in the first part of the book within the compass of forty-two very readable pages. In the second part Dr. Lamson gives a brief description of the electrocardiograph, and a more detailed account of the technic of interpreting polygraphic curves. The booklet can be highly recommended as an introduction to the study of cardiac irregularities.

TREATMENT OF HEART DISEASE

Médicaments et Médications Cardiaques. Par H. Vaquez. Paris: J. B. Bailliere et Fils, 1925.

This book is a compilation of the lectures of Professor Vaquez on the treatment of heart disease, made by one of his students, Dr. Theodoresco, and edited by Dr. Vaquez himself. It is written in a very readable, fluent style. The first chapter is devoted to a historical review of the clinical use of digitalis. The author then proceeds to discuss the pharmacodynamics and therapeutic indications of digitalis, strophanthus, and quinidine. In severe cardiac insufficiency with extreme dilatation Vaquez finds that digitalis does more harm than good. In such cases he asserts that very good results have been obtained from the use of ouabaine, but he emphasizes that it is essential to employ only ouabaine prepared from strophanthus glabre by the method of Arnaud. This drug is much less toxic than the other forms of strophanthin in common use. As a result of his studies Vaquez believes that the action of ouabaine is essentially on the ventricular musculature. He recommends its use in socalled acute cardiac dilatation with edema of the lungs, as well as in patients with severe persistent myocardial insufficiency in whom digitalis has proved of no effect. In the latter condition he gives ouabaine in doses of one quarter milligram intravenously morning and evening for two days, rarely longer. Further chapters cover the general regulatory measures employed in the treatment of heart disease, the treatment of insufficiency of the right and left hearts, of the arrythmias, of hypertension and angina pectoris. The book is scholarly, well written and most fascinating reading. It is quite distinctive in its field and should prove of value and of interest to every physician.

DYSPNEA

Dyspnea. By James Howard Means. Medicine Monographs, Vol. V. Baltimore: Williams and Wilkins Company, 1924.

This monograph contains much valuable information concerning dyspnea. The subject is a difficult one to the average physician who has had no special training in physical chemistry, and unfortunately Dr. Means has made its comprehension more difficult by an involved and at times, it must be said, a careless style. In the first section of the book the various factors that may be concerned in the production of dyspnea are discussed. The subsequent sections are devoted to an explanation of the causes of dyspnea in various diseased states.

RADIOTHERAPY

Ergebnisse der medizinischen Strahlenbeforschung (Röntgendiagnostik, Röntgenotherapie, Radiumtherapie und Lichttherapie). Herausgegeben von H. Hohlfelder, Frankfurt a.M., H. Holthusen, Hamburg, O. Jüngling, Tübingen, H. Martius. Bonn a. Rh. Band I. Mit 451 Abbildungen im Text und 3 photographischen Tafeln. Leipzig: Verlag von Georg Thieme, 1925. Pp. x-748.

The medical investigations in the realm of irradiation have enormously widened the scope of this branch of therapy, and investigators all over the world, working in the most diverse directions, have added considerably to the sum total of knowledge in this branch of medicine. Röntgenotherapy and radium therapy have been applied in all branches of medicine, and as a result the literature is distributed throughout the various special medical books and journals. The physical side of the subject, heretofore, had to be sought in the different journals of physics and were more or less inaccessible to the physician and surgeon. On the other hand, the physician and surgeon found themselves confronted by questions which really required a physicist to solve. It is only recently that physicists have begun to busy themselves with questions of this sort. The answers to numerous biological questions, which are intimately associated with histology, physiology and experimental therapeutics, are also distributed throughout the entire field of medical literature.

In order to overcome these difficulties of wide distribution, the editors of this encyclopedic work have assigned special subjects to authorities in their

respective fields and endeavored to present a complete view of irradiation therapy. In this first volume A. W. Fischer writes about the problems and results of röntgenological diagnosis of malignant and inflammatory tumors of the colon. E. Friedl discusses the subject of bone atrophy. Acute miliary tuberculosis in the röntgenogram is the work of A. Lorey. Spectroscopy in medical röntgenology, by L. Grebe, and the measurement of ionization of x rays, by H. Küstner, are worked up from the physical aspect. R. Glocker describes the means of protection from x rays and the construction and planning of x ray departments. H. Holthusen writes about physical sensitization. R. Schinz and B. Slotopolsky describe their work on the röntgenized testicle. W. Lahm discusses the irradiation treatment of carcinoma of the cervix uteri. The röntgen and radium treatment of carcinoma of the esophagus is contributed by H. Kurtzahn.

The bibliography is very complete, as is also the index of authors, in both of which English and American works are well represented. The same may be said of the subject index. On the whole, the least that can be said of this work is that no one who is interested in the subject of irradiation therapy can well afford to be without it. It is the most complete and up to date work on the subject known to the reviewer.

DYSPEPSIA

Lectures on Dyspepsia. By Robert Hutchison, M.D., F.R.C.P., Physician to the London Hospital. London: Edward Arnold & Co., 1925. Pp. 176.

This little book consists of a series of lectures on dyspepsia intended for audiences of British general practitioners. The subjects covered in the thirteen chapters are the clinical investigation of dyspepsia, the significance of abdominal pain, conditions which simulate dyspepsia, the organic dyspepsias, gastroptosis, the functional dyspepsias, special symptoms and their treatment, chronic diarrhea, chronic constipation, and mucomembranous colitis.

The style, as in practically all English books, is clear and pleasing. The last chapter on The Chronic Abdomen, which is as pretty a piece of English writing as we have seen in medical literature, has been the subject of editorial comment in the *Journal of the American Medical Association* (June 16, 1923) and of an interesting letter in a subsequent issue of the same periodical (July 14, 1923).

HAND INFECTIONS

Infections of the Hand. By Allen B. Kanavel, M.D. Fifth Edition, Thoroughly Revised. Illustrated with 196 Engravings. Philadelphia and New York: Lea and Febiger, 1925. Pp. 487.

It seems unnecessary to review the fifth edition of Kanavel's work. No man has done more to diminish the deplorable after results in traumatic conditions of the hand than Kanavel. The economic value in industrial medicine of his book is inestimable. Kanavel originally brought before the profession in this country the anatomy of the hand; pathology of infection of the hand; and, with the knowledge derived therefrom, a logical treatment of infections.

The fifth edition has been thoroughly revised, and takes up first, the simple infections, and later, the anatomy of the spaces of the hand and the tendon sheaths, describing in detail the courses of infections as they follow anatomical planes. This work is comprehensive, well written and delightfully combined with case reports which bring into play concrete examples. Kanavel's ingenuity in the many mechanical devices for correcting deformities of the hand is admirable. Every surgeon should thoroughly study this work because of its tremendous economic importance. A laborer with a stiff hand or finger presents immediately a serious economic problem in a community. To criticise a work of this type would be foolish; to give it sufficient praise is almost impossible.

SURGERY

Modern Surgery, General and Operative. By J. Chalmers Da Costa, M.D., LL.D., F.A.C.S. Ninth Edition, Revised and Reset. With 1200 Illustrations, Some in Colors. Philadelphia and London: W. B. Saunders Company, 1925. Pp. 15-27.

It is a great joy to welcome the ninth edition of Da Costa's *Surgery*. There is no single volume on surgery as thorough or as well arranged as Da Costa's. This new volume lives up to the standard set by its predecessors. Da Costa has the art of putting into a brief space a comprehensive description of a subject. Throughout the book there are numerous references to literature which will aid one to study monographs on the subjects described. The book is thoroughly up to date with adequate illustrations. The index alone must have been a colossal work as it occupies forty-two pages.

For the general practitioner, the student or the surgeon, the reviewer can recommend no finer one volume work on surgery.

MAYO CLINIC PAPERS

Collected Papers of the Mayo Clinic. Edited by Mrs. M. H. Mellish. Volume XVI, 1924. Philadelphia and London: W. B. Saunders Company, 1925. Pp. 1331.

This volume follows the practice initiated last year of including all the papers published from the Mayo Clinic, by either reprinting them in full, abstracting them or giving the titles only.

This year the miscellaneous group leads with forty-five titles. There then follow in order of amount of work represented, the alimentary tract with forty titles, the head, trunk and extremities with thirty-one, the blood and circulatory organs with twenty-four, the urogenital organs with twenty-three, skin and syphilis with seventeen, brain, spinal cord and nerves, and technic with fifteen each ,and the ductless glands with fourteen. As usual a complete bibliographic and author index still further enhances the value of this always useful volume.

THE COMMON COLD

Colds. Cause, Treatment and Prevention. By Russell L. Cecil, M.D. New York and London: D. Appleton and Company, 1925. Pp. viii-111.

Books couched in simple language, so as to be intelligible to the laity, are becoming increasingly popular and are a valuable means of educating the public in the matter of the conservation of health. This applies particularly to a book on colds—a practically universal ailment. The various types of colds and

their causes are discussed. The ordinary coryza is differentiated from hay fever and asthma, tonsillitis and adenoids, and grip and influenza. The complications of colds are also discussed. In the treatment and prevention of pneumonia, all the various forms of therapy from the old household remedies to the most recent chlorine treatment are mentioned. The reader is given reliable and comprehensive information in regard to the prevention and treatment of colds.

A SHORT HISTORY OF MEDICINE

Geschichtliche Entwicklung der Medizin in ihren Hauptperioden Dargestellt. Von Dr. Georg Honigmann. München: J. F. Lehmanns Verlag, 1925.

This brochure is not of the usual type of short history of medicine, but the author attempts to show the historical course of development of the ideas that run through medicine and their relation to the history of civilization. It is a sequel to his *Das Wesen der Heilkunde*. The author does not mention every prominent name in the history of medicine, especially of more recent time, but only shows the more important points of connection between the various periods of the development of medicine.

The different chapters are headed as follows: Primitive and Hellenic medicine, medical sects, Galen, and the medicine of the early Middle Ages; Arabian medicine and scholasticism; the Renaissance; the seventeenth, biological century; the eighteenth century; Romantic medicine in Germany; the beginnings of modern medicine; Virchow and cellular pathology; medicine in the age of materialism, and the development of the modern practice of medicine.

HANDBOOK FOR THE TUBERCULOUS

Recovery Record for Use in Tuberculosis. By Gerald B. Webb, M.D., and Charles T. Ryder, M.D.; Second Edition. New York: Paul B. Hoeber, 1925.

This is the second edition of an interesting book for tuberculous patients. The authors are both residents of Colorado and their personal as well as their general experience is of value in telling the patient how he can be helpful in his own case. The technic of recovery is comprehensively described so that any fairly intelligent patient can grasp the full meaning. Hygiene, diet, fresh air, food, the method of clothing are given so that the patient may make no mistake when he undertakes the cure. A number of chapters are devoted to a description of the kind of amusements the patient may indulge in. The meaning of symptoms, which the authors call accidents and obstacles, such as fever, sweating, hemorrhages, and colds, are described and how to avoid them explained.

The blank chart sheets, which make up the greater part of the book, are made interesting by quotations from well known tuberculosis authorities and classical authors. There are nearly one hundred record blanks on which the patient is to inscribe his daily temperatures, pulse, weight, and other items which he thinks might be of interest to the physician, or write questions he would like to have answered. Space would not permit to give the two quotations on each page although they are all interesting, educational, and even inspiring. Nevertheless, I may be permitted to quote a few particularly interesting ones. "I know I have hurt nobody by rest, but I am quite sure I often have by allowing them to exercise"—Trudeau. "To climb steep hills requires slow pace at first"—Shakespeare. "Even the father of medicine, Hippocrates, taught the value of fresh air" —Bowditch. "Too much food may prove as disastrous as too little food, it is a great pity to waste good food"—Lawrason Brown. "For tuberculosis we prescribe not medicine but a mode of life"—Bushnell. "It is in the power of man to cause all parasitic diseases to disappear from the world"—Pasteur. "I think we can see the beginning of the end of tuberculosis"—Miller. "This is a conflict which we may enter with a surely founded prospect of success"—Koch. The authors themselves give their final advice the words "Vive ut vivas" (Live so that you may live). It is to be hoped that these many interesting quotations, nearly all of them of an optimistic character, will suffice to counteract the inevitable harmful introspection which comes from the frequent counting of the pulse, taking the temperature, and watching the weight.

THE RECTOR OF WYCK

The Rector of Wyck. By May Sinclair. New York: The Macmillan Company, 1925. Pp. 258.

This short novel in Miss Sinclair's airier vein gives us another of her keen sidelights on life's ironies. Here is a girl of scintillant promise—she marries a country minister, such a nice fellow! Together in their uneventful country side they spend life—seemingly without results. As far as their dreams are concerned only one is left to them—their love of each other. Their children follow the more or less stereotyped rut of minister's children, not in this case because of severity in the home. There was none. Simply because nothing ever happens in that dead village. Two worthy people with whom fate deals most unworthily! Two selfless people who wear themselves out for others who would much prefer to be let alone.

Miss Sinclair is skillfully undermining age old precedent with the face of charming innocence. To some the *Rector of Wyck* will mercifully remain "a sweet story." Others it may tempt to thought concerning the pernicious "sweetness and light" ideals. Still others may with luck find inferences to draw about a few of the major hypocrisies of life, and ourselves as willing or unwilling victims.

A MYSTERY STORY

The Eames-Erskine Case. By A. Fielding. New York: Alfred A. Knopf, 1925. Pp. 244.

This is a mystery story of the standard double barrelled type. A young man is found murdered. It develops that he is the heir of a once famous house. He has been in Canada engaged in silk manufacture. He and his pal make discoveries that threaten to revolutionize the silk industry. The threads begin to weave back and forth with nothing as it appears to be. The difficult skein is at last unravelled to the satisfaction of all concerned (except the poor fellow murdered), the wicked suicide, in penance for years of vampiring, the good are rescued at the last, last gasp and consigned to the "happy ever after." An amusing tale, good enough for a desultory evening, and sufficiently full of subtle detail and mystery to confuse even a cross word puzzle fan.

Medicoliterary Notes.

"What would Abbas I, that mighty and terrible ruler of Persia some centuries ago, think of the modern world's annual consumption of cigarettes?" asks a recent issue of the *New York Times Magazine*. "It was Abbas who cut off the lips of those of his subjects who smoked and the noses of any who ventured to take snuff. Once he found a man selling tobacco and threw man and weed together into the fire. In 1610 Mohammed IV punished a citizen of Constantinople who, contrary to the royal edict, was discovered smoking by ordering a hole pierced through the cartilage of his nose and a pipe inserted into it. The offender was then seated on the back of an ass, with his face toward the tail, and driven through the streets of the city, while the town criers announced his crime and punishment. Czar Michael Fedorowitz of Russia not only had his subjects beaten publicly for smoking, but often went even further; and were this crime committed a second time, death was the penalty. . . .

"It is a long jump from his time to 1908, but in the latter year writers in this country were beginning to comment unfavorably on women smoking. One commentator of that date, referring to the "unlovely" list of feminine smokers, stated there were to be found on it names of many women of renown. He had been told the Empress of Austria smoked from thirty to forty cigarettes daily. The Dowager Empress of Russia was also addicted to the use of the weed, as well as the Queen of Rumania, the Queen Regent of Spain, the Queen of Italy, and the Queen of Portugal. The latter, however, came honestly by her smoking proclivities, her mother being a devotee of the weed.'

"Today the situation is startlingly altered, and critics of bygone times might discover themselves at a loss for words as they surveyed the modern inroads of tobacco. . . . Difficulty in securing even an eligible executioner would complicate the case."

* * *

Aesculape (Paris) for March, 1925, contains a number of articles of rather exceptional interest, with the usual excellent illustrations marking that publication. Among the articles are: *Le Cure de Syphilis en XVI ièmé Siécle*, Dr. E. Jeanselme; *La Lèpre en Catalogue au Temps Jadis et de Nos Jours*, by Dr. J. Sabrazès; *Lesb Femmes à Barbe*, by Dr. Laignel-Lavastine; *Les Lépreux en Bas-Limousin*, by Prof. Guiart and Dr. Jean Mazeyrie; *Nègres Blancs et Nègres Pies*, by Dr. Neveu-Lemaire; and *La Maladie de Job*, by Prof. J. Rollet.

* * *

In Fridtjof Nansen's recently published book, *Hunting and Adventure in the Arctic*, quite a detailed description is given of the very distressing and heartless wholesale destruction of seals going on there. The author does not mince matters in commenting on the terrible cruelties practised, and their effects upon the natures of the seal catchers. He once asked a captain of a sealing vessel whether this wholesale slaughter would not exterminate the seals. "No, lad," replied the captain, "Providence created the seals for us to catch, and Providence will see to it that they don't grow scarce." Nansen makes another plea for the preservation of the whales, which are rapidly being extirpated. "We cannot even agree to spare them sufficiently to keep them in existence so that they may be of lasting certain utility to us. It seems as though human beings in their insatiable greed are wilfully blind."

* * *

A strong prohibition movement is being staged in India, notably in Bombay, and its victory has been described as within measurable distance. The British press seems to consider the movement as of purely political origin, an outcome of the noncooperative program.

* * *

The latest *Bulletin* of the Eugenics Record Office is one of unusual interest. It is a study of Body Build: Its Development and Inheritance, by C. B. Davenport, director of the department of genetics of the Carnegie Institution of Washington.

* * *

The Grand Street Follies, third edition for 1925, at the Neighborhood playhouse is about the cleverest and most entertaining show of the kind that has appeared before the footlights of New York theatres this season. The acting has a freshness and individuality seldom seen on the professional stage, and most of the impersonations are excellently done. "They Knew What They Wanted Under the Elms" starts the ball rolling in a very clever and amusing way.

* * *

It is reported in Prague that a large collection of Dostoievsky manuscripts has been found in the Caucasus. Included are said to be two unpublished works. The story is that the author himself deposited this material in safes in Moscow and Petrograd. When he died his widow went to live in the Caucasus, taking the keys with her. She, in turn, died without formally mentioning the manuscripts. . . . Recently they were found, the report goes, in an old box which had been placed in storage by a man, supposedly a stranger to the Dostoievsky family.—*New York Times.*

* * *

The recently issued Annual Report of the New York State Hospital Commission for 1923-1924 includes some interesting figures on results of treatment. The cases discharged from the civil state hospitals, exclusive of transfers, numbered 4,396. Of these 1,720 were discharged as recovered, 991 as much improved, 987 as improved, 618 as unimproved, and 80 as not insane. The total discharged benefited by treatment was 3,778.

* * *

Late publications of interest to physicians are *The Taxonomy of Poison Ivy*, by James B. McNair (Field Museum of Natural History, Chicago); *The Adolescent Girl*, by Winifred Richmond (Macmillan); *Social Psychology*, by Knight Dunlap (Williams & Wilkins). Announcements for early fall include *Rejuvenation by Grafting*, by Dr. Serge Voronoff (Adelphi).

* * *

The Hygienic Laboratory of the U. S. Public Health Service has issued the following *Bulletins:* The Use of Cooked Meat Medium for the Detection of C. Tetani; Studies on the Potency Testing of Pneumococcus Vaccines; The Adaptability of Various American Peptones for Use in Cholera Media, all three by Ida A. Bengston; Active Immunization of Monkeys Against Pneumococcus Pneumonia by Means of Intratracheal Injections of Pneumococcus Vaccine; Treatment of Experimental Pneumococcus Pneumonia in Monkeys with Pneumococcus Antibody Solution, both by Russell L. Cecil and Gustav I. Steffen: The Fate of Pneumococcus Protective Bodies When Injected into Normal Animals, by Dorothy R. Rhoades; The Protective Substance in Pneumococcus Pneumonia; The Use of Optochin Base in the Treatment of Lobar Pneumonia.

* * *

After five years of legislative activity, the venereal control bill for the District of Columbia was signed by the President on February 26th. In spite of the fact that the bill had been on the verge of enactment at several times previously, it did not become a law until the closing days of the Sixty-eighth Congress, although every state in the Union had had some sort of venereal control measure since 1921.

* * *

The new headquarters of the British Medical Association shortly to be opened by the King occupies a site in Tavistock Square on which once stood Dickens' house before he moved to Gadshill. The actual site of the house is now covered by a sunken garden, but it is reported that the tree under which Dickens used to love to sit has been preserved. It has been proposed that a memorial be set up to mark the position of the house and record its significance as a literary landmark. It was Dickens' last permanent home in London.

* * *

The New England Peabody Home for Crippled Children has recently issued an attractive report covering the years 1924-25, and describing and illustrating the work done there.

* * *

The June issue of *Surgery, Gynecology and Obstetrics* is its twentieth anniversary number. In addition to the regular departments, there are articles by Dr. Franklin H. Martin of Chicago, on *Surgery, Gynecology, and Obstetrics*, Twenty Years Old; Dr. William J. Mayo, of Rochester, Minnesota, on Progress of Surgery in the Last Two Decades; and Sumner L. Koch, of Chicago, on Twenty Years of Surgery and an Index. In the department, The Surgeon's Library, is an especially interesting article on Lithotomy and the Lithotomists, by Dr. Alfred J. Brown, of Omaha, with two full page reproductions of old engravings.

Abstracts from Current Literature

CARDIOVASCULAR DISORDERS

Acute Coronary Obstruction.—Frederick A. Willius (*Medical Clinics of North America,* January, 1925) states that there is little to be done for this condition except to alleviate the patient's suffering as much as possible. The administration of morphine is probably the most effective for this purpose. In the author's experience the nitrites have given little or no benefit. The application of leeches to the precordium has been recommended. If the patient survives the severe cardiac insult, and there are manifestations of myocardial failure, the use of digitalis is indicated. The dose and method of administration must always be determined by the circumstances in the individual case. The presence of a pericardial friction rub due to localized pericarditis over the infarcted area is strong confirmatory evidence, but its absence is not significant. The rub is usually heard over the lower sternum, or just to the left of the sternum.

Premature contractions are frequently present, but their occurrence is not diagnostic. Most râles at the base of both lungs is a common finding. Fever, ranging from 99.6° to 103° and 104° F., is quite the rule, appearing a few hours after the accident. There is usually a definite leucocytosis, the count varying from 11,000 to 25,000. The electrocardiograph is helpful in substantiating acute coronary obstruction. The most constant findings in thirty-one reported cases were changes in the T wave, consisting of negative, diphasic and isoelectric deflections in Derivation I, in Derivations I and II, in Derivations II and III, and in Derivations I, II and III. In four cases, fusion of the R and T waves occurred, and in five instances aberration of the QRS complexes in all derivations were recorded.

Digitalis: Its Untoward Effects and Conditions Under Which It Either Fails to Act or Produces Unfavorable Results.—Henry K. Mohler (*Medical Clinics of North America,* November, 1924) states that the extraordinary difference in the results obtained from the use of digitalis often is difficult to explain. Different patients complaining of like symptoms and suffering from identical heart lesions respond to digitalis in a most variable manner.

The rapid heart rate, noted in neurocirculatory asthenia and in hyperthyroidism, not only is not benefited by digitalis administration, but accompanying symptoms are often aggravated. The tachycardia of hyperthyroidism is probably not benefited unless it is due to auricular fibrillation. The use of digitalis has not been of any uniform value in the treatment of paroxysmal tachycardia unless the duration of this disorder has inaugurated or aggravated a myocardial failure.

The heart failure seen in postoperative surgical infections, especially acute peritonitis, is seldom benefited by the administration of digitalis. The intravenous use of digitalis under these circumstances is especially dangerous because of the possibility of full doses producing the condition which is usually fatal, viz., ventricular fibrillation.

Patients who suffer from attacks of angina pectoris and who are treated with the usual doses of digitalis during the interval of the attacks, are often made worse.

In the form of cardiac irregularity known as sinus arrhythmia digitalis is without effect and may produce extrasystoles and more forcible action of the heart and even partial heartblock. Partial heartblock, a condition in which the ventricles fail to respond to every second, third, or fourth auricular contraction, may be converted into a complete block by the use of digitalis.

In auricular fibrillation digitalis may fail to produce a good result if the pulse rate be taken as the guide rather than the heart rate. Digitalis, if it is used in the treatment of this disorder, to be most effective must lower the heart to a range of sixty-five to seventy-five a minute. When the contractile power of the heart muscle is exhausted, digitalis may slow the pulse rate of auricular fibrillation to within normal range, but with no improvement in dyspnea, edema, and other accompanying symptoms. Cases of auricular fibrillation with heart failure and slow pulse rates are usually not benefited by the administration of digitalis.

Disappointment is often experienced in the intravenous use of digitalis in cases that appear to be heart failure. Sudden interference with the coronary circulation is accompanied by acute precordial pain and symptoms of heart failure. The use of digitalis under these circumstances is usually of no value and may produce ventricular fibrillation, a condition which is usually fatal and frequently present in preagonal states.

Digitalis fails to act or its action is delayed because the dose is too small or it is not absorbed. If considerable edema is present, absorption from the alimentary tract, when digitalis is given orally, and from edematous tissue when given subcutaneously, is very much delayed, and occasionally intravenous methods may be necessary to produce effects within several hours. When the symptoms are urgent the drug should be given so that the adult patient absorbs from four to eight c.c. of the tincture within twenty-four hours. In auricular fibrillation, if the digitalis is continued over too great a time or the doses are too large, "coupling of the beat" may be produced, and the patient complains of precordial distress, dyspnea, fulness in the head, and syncopal attacks or vertigo. The symptoms of digitalis poisoning are nausea, vomiting, diarrhea, headache, and dimness of vision.

Failure to obtain results from digitalis administration may result because poor preparations of digitalis are supplied. Tincture of digitalis, or the powdered digitalis leaves, physiologically assayed, have produced the best results by oral administration. For subcutaneous or intravenous injection suitable preparations of digitalis are manufactured, but one should be familiar with their action before too much reliance is placed upon them. Tincture of digitalis is more effective when administered not in combination with other drugs.

Digitalis will not act effectively in the presence of fever. The heart of diphtheria patients should be very carefully studied before digitalis is used, lest distressing symptoms may result. The cumulative effect of digitalis is probably not as great as it has been thought to be. The sudden disappearance of extensive edema, when digitalis has been taken over a long period of time, may result in the rapid absorption of the drug, producing symptoms of digitalis poisoning. Certain persons do not tolerate digitalis at times. This peculiar action may be explained by an idiosyncrasy for this drug.

Essential Hypertension.—Henry D. Jump (*Medical Clinics of North America,* November, 1924) describes essential hypertension as a disease in which blood pressure is increased and in which there is primarily no distinctive pathology or known cause. It is not generally recognized that hypertension may be the primary condition which will produce pathological changes in the vessels and kidneys. It is usually benign and subject to relief, but, on the other hand, consequences may follow rapidly and extensive damage occur.

The immediate cause of hypertension is probably a spasm of the smaller bloodvessels. The increased resistance calls for increased pressure in order to maintain the circulation correctly. The causes of this spasm must be various. An important factor is physical and mental strain, particularly the latter. Persistent overeating appears in some cases to be a positive factor. It is significant that persons with intestinal stasis frequently have increased pressure. Excessive use of tobacco appears to be a cause. It is still a debatable question how far alcohol may be considered as causing hypertension. The menopause has lately been thought a cause, and particularly when it is accompanied by obesity. The altered function of the ductless glands which accompany the menopause probably exert some influence upon blood pressure. Essential hypertension is a disease of middle life, though it is occasionally met with in the young.

Persistent increase in arterial tension may exist without any symptoms in the early stages. It may be discovered accidentally. Fatigability and vertigo are among the earliest symptoms; lack of initiative in mental and physical exertion are frequently noted. These symptoms seen in association with nervous instability may lead one to confuse the disorder with neurasthenia. Involvement of the heart leads to palpitation, irregularity, and dyspnea. The symptoms referable to the hardening of the bloodvessels vary with the location of the vessels involved. If of the abdomen, distention and other evidences of indigestion; if of the kidney,

the symptoms of contracted kidney—edema and urinary changes; if of the brain, symptoms of hemorrhage and thrombosis. In advanced hypertension headaches may be persistent and severe—the socalled "lead cap headaches." The sequelæ include hypertrophy of the heart and ultimately myocarditis, sclerosis of the bloodvessels and, secondarily, arteriosclerotic kidney.

Treatment depends upon an early discovery of the condition by routine physical examinations. An increase of twelve mm. above the average blood pressure appears to indicate the limit of normal excess. Reduction measures must be entered into guardedly and in association with removal o causes. Focal infections must be persistently sought for and removed. Strain and worry must be eliminated. A period of complete rest in bed on a milk diet will effect a very good reduction. Exercise should be indulged in to such an extent as the patient's condition permits. It should never be hurried. Foods which disagree with the patient must be avoided. Abstinence from proteins is helpful. A milk and vegetarian diet is best. Coffee, tea and alcohol should be avoided. Constipation should be eliminated. Colonic irrigations are helpful. An occasional mercurial purge is of advantage. Tobacco should be used sparingly or not at all. Obesity should be reduced moderately. Patients must not be so greatly reduced as to impair strength and vitality. Pilocarpine hydrochlorate in doses of one twentieth grain every three hours promotes diuresis; in larger doses up to one tenth grain it causes free sweating or free secretion of the gastrointestinal glands and kidneys. The bromide salts serve a very useful purpose in controlling excitement and apprehension. The vasodilators are occasionally indicated. Of these, potassium or sodium nitrite, in doses of one half to two grains every three hours, and erythroltetranitrite, in doses of one half to two grains every three hours, are the best.

Myocardial Infarction: An Electrocardiographic Study.—Frederick A. Willius, and Arlie R. Barnes (*Journal of Laboratory and Clinical Medicine,* March, 1925), describe nine cases of myocardial infarction from the Mayo Clinic, giving the electrocardiographic findings, and review twenty-four published cases. The most striking changes are those affecting the T wave; such abnormalities occurred in twenty-six of the thirty-one cases. In one instance the electrocardiogram was normal. The most frequent change found was the negativity of the T wave involving Derivation I, combined Derivations I and II, combined Derivations II and III, and combined Derivations I, II, and III. In three cases, the derivations involved varied during the period of observation; in four cases a tendency for fusion of the R and T wave occurred as a transient manifestation, quite closely resembling the findings of Pardee. Notching and broadening of the QRS complex involving all derivations occurred in only one instance in their own series. The other findings, delayed A-V conduction, sinoauricular block, ventricular tachycardia, nodal tachycardia and auricular flutter, occurred with such infrequency as to be unimportant. The frequency of T wave changes in myocardial infarction the authors believe to be significant, and these findings, in the presence of a suggestive clinical syndrome, will undoubtedly increase the frequency of a correct clinical diagnosis.

Importance of the Blood Pressure in the Progression of Glaucoma.—P. Baillart (*Médecine,* January, 1925) points out that the degree of excess of the intraocular tension is not the only factor bearing on the progression of glaucoma. The visual disturbance being due to compression of the retinal arteries on account of the increased intraocular tension, the lower the original pressure in these arteries the more pronounced will be the effects of the pressure exerted on them. A person with a normal pressure in the retinal arteries—about 30 mm. Hg, diastolic—will be seriously disturbed by a rise of intraocular tension to 45 mm. Hg, while a person with high blood pressure and consequently a high pressure in the retinal arteries will hardly at all be inconvenienced. As soon as the intraocular tension reaches the diastolic pressure in the retinal arteries, circulatory disturbance, with all its consequences, appears. It is not even necessary to determine directly the retinal arterial pressure to ascertain just where this zone of danger begins. Tests showed that the diastolic retinal arterial pressure is approximately one-half of the diastolic pressure in the brachial artery. Thus, whenever the intraocular tension reaches one half the latter pressure, there is risk of the retinal arterioles being forced shut during diastole, so that the circulation in the retina is insured only during systole. If the ratio of intraocular to arterial tension rises still further, the circulation is more and more disturbed, alike as regards the choroid circulation, which participates in regulation of the intraocular tension, and the retinal circulation. A time comes when the veins themselves are forced shut, the return circulation is arrested, and the resulting disturbance leads not only to loss of vision, but also to redness of the eyeball, edema of the humors and a fresh elevation of intraocular tension. It is a mistake to consider glaucoma as a complication of high blood pressure; many glaucoma cases have never had a high blood pressure, and acute attacks of it are seen even in persons with low blood pressure.

Value of Vital Capacity Charts in Diseases of the Heart, Lungs, and Mediastinum.—John H. Arnett (*Medical Clinics of North America,* November, 1924) states that in diseases of the heart, lungs, and mediastinum there may be a very marked reduction of the vital capacity, and that therefore this determination cannot be used to make a differential diagnosis between these three conditions; neither can it be used to diagnose the particular pathological processes which may involve the heart, lungs, or mediastinum.

Vital capacity standards, when applied to healthy individuals living under relatively uniform conditions, show variations of such frequency and degree that even the best standards must be regarded as an inaccurate estimation of the vital capacity which a healthy person should possess. Our vital capacity standards must be regarded as extremely rough and inaccurate means of estimating a person's normal vital capacity, and therefore we must admit that our present standards possess a very limited value in the diagnosis of diseases of the chest.

However, it is often valuable to have a rough estimation of what the vital capacity in a given case should be. For this purpose the author believes that a standard based upon height alone is more satisfactory than one based upon weight, either alone or combined with the height, as in West's surface area standard, for example. This is true because this surface area standard assumes a normal relationship between height and weight, which in many patients in a hospital ward does not exist. The weight throws a confusing element into the standard. Furthermore, since simplicity is always an important factor, it seems more rational to use a simple height formula, such as that recommended by Peabody and Wentworth, West, or Hewlett and Jackson. Be that as it may, the important thing to remember about vital capacity standards is their unreliability, unless applied only to the group from which they were derived.

Aside from the question of standards, however, the vital capacity possesses a definite value in following the course of patients with diseases of the chest; it offers likewise a method of studying their pathological physiology. Furthermore, by watching the vital capacity of our private patients from year to year, a sudden reduction, which cannot be otherwise accounted for, may perhaps be a valuable early indication of incipient pulmonary disease.

The Basal Metabolic Rate in Cases of Primary Cardiac Disease.—Walter M. Boothby and Frederick A. Willius (*Medical Clinics of North America,* January, 1925) report that in the routine determination of the metabolic rate in patients with cardiac disease, the level of the metabolism is found to be slightly elevated above the DuBois standards more frequently than in strictly normal subjects. This elevation is independent of electrocardiographic findings, and of the type, character or degree of the organic heart lesion. Patients, however, who present evidences of marked cardiac decompensation in the form of dyspnea or orthopnea occasionally have a definite increase in metabolism; in such cases the metabolism usually decreases as cardiac efficiency improves. However, the relative infrequency and irregularity of the increase in metabolism, with or without cyanosis, is against the assumption that the usual cause is the formation of lactic acid from incomplete oxidation, although in a case of extreme cyanosis this might occasionally play a slight part. In the authors' cases the most probable causes seem to be based on two factors: the actual increase in muscular work required in labored respiration, and, which is more important, a subjective sensation of distress, with resultant nervousness and fear, from the application of the mask. Consequently, it is often difficult to obtain sufficient coöperation from the patient, to assure complete mental and physical relaxation. Likewise, patients with hypertension and

a very high diastolic blood pressure are likely to have an elevation in the metabolism, apparently in most cases because they can less readily relax, although other unknown factors may play a part.

On account of the relative frequency of a slight elevation in the metabolic rate in patients with cardiac disease, due, as a rule, to the difficulty of establishing standard conditions, it behooves the physician to exercise great caution in interpreting the clinical significance of slight elevations in the metabolism in patients suffering from decompensated heart disease or essential hyperthyroidism.

On the other hand, in many cases of adenomatous goitre with hyperthyroidism, the correct diagnosis may be overlooked. A patient with an adenoma of the thyroid, especially if the tumor is quite small, must be considered as hyperthyroid, and the cardiac condition regarded as entirely or partly secondary thereto, provided the metabolism on repeated observations remains above normal.

Fate of the Bulbus Cordis in the Human Heart.—Arthur Keith (*Lancet,* December 20, 1924) adduces evidence which seems to him to demonstrate that the infundibulum of the right ventricle must be regarded as a distinct constituent of the heart, as evidenced by studies in comparative anatomy and embryology. A survey of the anatomy of the infundibulum shows that, although its cavity is now merged into that of the right ventricle, its limits can still be identified. The evidence which is still lacking relates to the exact function of this part of the heart. The evidence of comparative anatomy leads one to regard it as serving as a safety mechanism for the pulmonary circulation. In the mammalian heart the musculature of the infundibulum passes into action later than that of the body of the right ventricle. The author believes that future investigations will show that the infundibular chamber and its musculature only come into effective action during periods of great exertion and stress. At rest the right ventricle of a man pumps about three litres of blood into the lungs a minute, but in periods of stress, the output may rise to thirty litres a minute. In such conditions of cardiac stress the cavity of the infundibulum intervenes between the driving power of the right ventricle and the pulmonary circulation, and must, the author thinks, exercise a moderating influence.

Premature Heart Beats.—John Hay (*British Medical Journal,* October 18, 1924) classifies the more common cardiac irregularities into two groups: 1, Sinus arrhythmia, with a rise and fall in frequency associated with respirations, and the arrhythmia due to premature beats; 2, auricular fibrillation and pulsus alternans. Other things being equal, the prognosis in the first group may be good. The finding of premature beats indicates a careful physical examination, especially in advanced years. The prognosis depends upon the associated conditions. In the second group, much depends upon the amount of distress from the fibrillation; the condition of the myocardium may be judged thereby. Another guide is the ventricular rate—the greater the rapidity, the more grave the prognosis. An absence of response to digitalis is a grave omen, particularly if the fibrillations are superimposed upon a high blood pressure. It is very important to recognize the nature of the irregularity.

Cervical Sympathectomy in Angina Pectoris.—F. J. Smith and R. D. McClure (*Surgery, Gynecology and Obstetrics,* August, 1924) assert that while in many cases resection of the cervical sympathetic in angina pectoris, unilateral or bilateral, may greatly lessen the number and minimize the intensity of the painful attacks, it must not be counted on to secure complete relief from pain, unless the first thoracic ganglion is included in the resection. The resection should be done first on the side which has shown the greatest or most severe radiation of pain, and followed later by a similar operation on the other side, if complete relief is not obtained after the first one.

As has already been pointed out by Jonnesco, more favorable results may be expected in those persons in whom the painful attacks dominate the picture, while the cardiac compensation is good, than in the patients who give evidence of grave heart muscle damage or are already in a state of cardiac failure.

The main indications for operation are: 1. Frequent and severe attacks necessitating the giving up of occupation, and not yielding satisfactorily to medical measures. 2. A feeling on the part of the patient that the painful attacks provide an intolerable situation.

Cardiac Irregularities: Especially in Reference to Prognosis and Treatment.—T. Wardrop Griffith (*British Medical Journal,* October 18, 1924) calls attention to the fact that some cases of extrasystole appear to be unimportant, but they occur more often in persons with cardiac, valvular or muscular lesions and hypertension, that they often persist in spite of treatment, that they may be associated with severe distress, and that they may lead to a severe neurosis. In general, the prognosis depends more on the condition associated with the extrasystole than with the actual irregularity itself. In the absence of organic disease of the heart, open air pursuits may be followed and a reasonable amount of exercise taken. A light diet is indicated. Oral sepsis should be corrected. Coffee should be avoided and tobacco limited. Great benefit is said by some to result from small doses of quinidine, both in extrasystoles and in paroxysmal tachycardia. In paroxysmal tachycardia the symptoms may be alarming and even fatal. The various maneuvres recommended include firm pressure on the abdomen, and holding the breath after a full inspiration. The author has obtained some excellent results with hypodermic injections of morphine.

The prognosis of pulsus alternans is grave. A short period of pulsus alternans may follow premature systoles without any serious portent, but if it persists the outlook is serious. Intercalated extrasystoles, too weak to be detected at the wrist, may simulate this condition. It may also be found after the use of atropine. If these conditions can be eliminated, serious myocardial disease should be suspected.

Thyrocardiacs.—F. H. Lahey and B. E. Hamilton (*Surgery, Gynecology and Obstetrics,* July, 1924) note that the effect of prolonged thyroid intoxication upon certain individuals is to produce auricular fibrillation, and eventually true heart failure. In these cases even partial restoration of compensation may quite safely be followed by thyroid surgery, in properly selected stages. Subtotal thyroidectomy in such thyrocardiac cases relieves the failing heart of the burden that is making it fail and results in nearly all cases in complete relief of a complete disability. There is no comparable condition where persistent heart failure is consistently and safely cured by surgical measures.

This group of thyrocardiacs represents in a sense a new field for surgery, small but intensely fertile. It should stimulate everyone who has to deal with patients suffering from disability associated with heart failure, to consider carefully that an underlying hyperthyroidism is not overlooked.

Sensory Nerve Fibres of the Heart and Aorta in Relation to Surgical Operations for the Relief of Angina Pectoris.—J. N. Langley (*Lancet,* November 8, 1924) asserts that the cardiac afferent fibres existing in the sympathetic nerve can be severed without interfering with the innervation of the head, neck, or forelimbs by cutting the major and minor accelerator nerves (most of these are probably in the major nerve), but this would sever also the known sympathetic fibres both afferent and efferent of the head, lungs, and thoracic part of the esophagus. From an operative point of view the simplest procedure is to cut the nerves passing medially from the stellate ganglion, leaving intact the vertebral nerve and other rami communicantes. This, however, severs the sympathetic fibres to the head as well as those to the thorax. In the cat it is a very simple operation, and in those cases in which it has been performed it has not been found to have any fatal effect.

Points of Action of Phenobarbital and Sodium Phenobarbital in Lowering Blood Pressure.—Charles M. Gruber and Roy F. Baskett (*Journal of Laboratory and Clinical Medicine,* May, 1925), from experiments on dogs, cats, and rabbits, found that the usual effect of the intravenous injection of phenobarbital and sodium phenobarbital was to slow the heart rate; the heart's force was diminished and the heart itself dilated slightly when acted upon by sodium phenobarbital. There appears to be a greater depression of the cutaneous vessels than of the visceral vessels; the vessels of the limb dilate, while those of the intact intestine, kidney and spleen constrict. However, perfusion experiments show that the vessels of the kidney may also dilate and those of the limb may constrict. Sodium phenobarbital in moderate doses has no direct action upon the secretion of urine, although if given in large doses the resulting fall in blood pressure is capable of decreasing the urine secretion even to the point of causing anuria.

Direct Injection Into the Heart for Arrest of the Heart Beat During Anesthesia.—W. B. Howell (*Lancet,* October 11, 1924) states that when breathing stops during anesthesia, the first thing to do is to ascertain the condition of the heart, for no amount of artificial respiration will oxygenate blood which is not circulating. Time spent in giving hypodermic injections, hot applications, and other restorative measures is merely compromising the chances of recovery.

The actual injection is apparently harmless. At necropsies the damage from cardiac injections has been found to be *nil* as compared with that following cardiac massage. The needle should be inserted into the fourth intercostal space at the upper edge of the fifth rib, close to the sternal border, or else one finger's breadth inside the left border of relative heart dullness. By the first route, the right ventricle, and by the second, the left ventricle is reached. By either the internal mammary artery is avoided. The needle is known to be in one of the cavities of the heart by the escape of blood when the stylet is withdrawn. If the heart is much distended with blood it may be of advantage to let some of the blood escape. It would seem most rational to make the injection into the heart muscle itself. The injection can be conveniently made by means of a spinal puncture needle. Other substances than adrenalin have been used, but none has proved so satisfactory. The best method of artificial respiration is by means of the intratracheal insufflation of air. Sylvester's method has the drawback of hampering the heart by means of pressure on the lower thorax.

Relationship Between Calcification of Costal Cartilage and Bloodvessels (in Arteriosclerosis).—Charles A. Huyssen (*Schweizerische medizinische Wochenschrift,* October 31 and November 6, 1924) states that calcification of the costal cartilages, with the exception of the first on both sides, justify, in so far as they reach a certain extent, the assumption of a calcification of the internal bloodvessels (in the sense of arteriosclerosis). Calcification of the costal cartilages of lesser grade develop also as signs of senescence and as a result of disease conditions, which produce a protracted malnutrition of the body; with a coincident arteriosclerosis the calcification of cartilage is especially extensive in these cases. The grade of calcification of the costal cartilages must be judged differently according to the age and, especially, to the sex of the patient; it increases with age (even without vascular changes) and is usually considerably less extensive in females than in males. Coronary sclerosis in both sexes appears to show a generally more extensive calcification of costal cartilages than the average of the other forms of arteriosclerosis. In intermediate cases, with and without arteriosclerosis, occurring in patients of the same age and sex, the difference in the calcification of the costal cartilages in the röntgenogram of the isolated anterior chest wall can always be easily determined, but special attention must be paid to the calcifications in the sternal portion of the cartilages. If the röntgenologist can sufficiently demonstrate the calcification *in vivo,* the calcifications of the costal cartilages can aid in the diagnosis of arteriosclerosis after the normal values are determined.

Paroxysmal Tachycardia.—Frederick W. Price (*British Medical Journal,* October 18, 1924) classifies all cardiac irregularities as follows: 1, socalled sinus irregularity; 2, irregularity due to premature contraction (extrasystole); 3, irregularity due to heart block (sinoauricular, auriculoventricular, or intraventricular); 4, irregularity due to pulsus alternans; 5, irregularity due to auricular fibrillation; and 6, irregularity due to auricular flutter.

The author believes that the term paroxysmal tachycardia should be applied to marked acceleration of the cardiac rate, which commences suddenly without apparent cause, lasts for a varying period, ceases suddenly, and is due to an abnormal rhythm. The vast majority of such cases are the result of temporary auricular flutter with tachycardia, or temporary auricular fibrillation with tachycardia, and also paroxysms of extrasystoles. This condition should be suspected whenever an individual is conscious of a marked increase in the cardiac rate or attacks of palpitation occurring suddenly and without apparent cause, or suffers from dyspnea on exertion, and other indications of cardiac failure coming on rapidly. Some cases can only be diagnosed with the electrocardiograph.

The most important diagnostic factors are: the commencement and termination of the attack of tachycardia, characterized by the abruptness of the onset and termination, the reaching of the maximum rate within a few seconds; a persistent rate of over 160 and even of 140; the cardiac rate is not influenced by a change of posture or other forms of physical exertion. Recently the author has successfully employed five grains, after a preliminary dose of three grains to test for possible idiosyncrasy, of quinidine once daily, in the intervals between attacks, and to prevent their recurrence.

Microscopically Demonstrable Fat in Normal Human Heart Muscle.—A. M. Master (*Journal of Laboratory and Clinical Medicine,* May, 1925) found in a study of thirteen hearts from persons who had met sudden violent death by bullet, stab wounds, or other means, minute red droplets by the scharlach stain in the sarcoplasm of the cardiac muscle cells. These persons ranged from eight to fifty-six years of age. The socalled pigment of brown atrophy, supposedly an indication of senility of the muscle, was found in two healthy boys, eight and fifteen years old, respectively. The picture presented by the diffuse red droplets closely resembled the classical illustration that many of the textbooks on pathology use to depict fatty degeneration of the heart.

Notes on Acute Rheumatic Disease of the Heart.—William S. Thayer (*Bulletin of the Johns Hopkins Hospital,* February, 1925) presents a critical analysis of twenty-five cases of acute or subacute endocarditis coming to autopsy which appeared to be of indisputably pure rheumatic origin without demonstrable complicating bacterial septicemia. In twenty-one of these cases characteristic Aschoff bodies were found in the heart muscle. While the etiological element was not apparent, the sequence of the disease on ācute tonsillar or nasopharyngeal infection was striking. The onset was often associated with acute articular rheumatism or chorea. Thayer concludes from his analysis of these cases that the rheumatic origin of the manifestations of acute heart disease must naturally be regarded as probable when these are associated with polyarthritis or chorea. When, however, neither arthritis nor chorea is evident, a rheumatic carditis may be suspected from the youth of the patient, the history of previous arthritis or chorea, the evidences of tonsillitis, negative blood cultures, the frequency of serofibrinous pericarditis, relatively rare in acute and subacute bacterial endocarditis, the pronounced leucocytosis and the absence of petechiæ, or evidence of splenic enlargement, embolic phenomena or of blood in the urine. Especially significant, however, are electrocardiographic changes or the early onset of failure of the heart muscle, which reveal the presence of myocardial involvement, much more common in rheumatic disease than in other cardiac affections.

Acclimatization to High Altitudes.—J. S. Haldane (*British Medical Journal,* November 15, 1924) asserts that when we regard as a whole the phenomena of acclimatization to a low atmospheric pressure we see at once that when acclimatization is complete the organism is still in a physiologically different state from what it was before exposure to the low pressure. The breathing is greatly increased; the concentration of the blood in hemoglobin and red corpuscles is also increased, as well as the blood volume; the blood plasma is altered in composition; the blood forming bone marrow is increased; and if we could detect them we should probably find histological changes in the lung epithelium. All these changes, and probably many more which are not yet discovered, quite evidently centre around what may metaphorically be called an attempt to keep the oxygen pressure, and simultaneously the hydrogen ion concentration, about and within the living tissues constant. But the attempt is not completely successful: a slight deficiency in both oxygen pressure and hydrogen ion concentration remains over, and doubtless becomes more appreciable the greater the altitude. This deficiency is necessary as the stimulus for maintaining the state of adaptation. The primary stimulus is the deficiency in oxygen pressure, and the hydrogen ion deficiency is secondary to this. If we ask why the hydrogen ion deficiency at least should not be fully compensated, the probable answer is that this would involve such a loss of sodium, and perhaps potassium, as is resisted. Although from its very nature the process of acclimatization cannot be theoretically complete, yet it has the unmistakable effect of keeping the oxygen pressure within the body approximately constant without more than slight disturbance of other important factors in environment.

Medicolegal Notes.

SUFFICIENCY OF INDICTMENT UNDER HARRISON ACT

Section 2 of the Harrison Act prohibits the sale of narcotics, except on written order of the purchaser on a prescribed form. Section 6 exempts sales of certain remedies when sold as medicine, and not for the purpose of evading the act. Section 8 provides that in indictments "it shall not be necessary to negative any of the aforesaid exemptions." In a prosecution against a registered druggist for selling paregoric containing two grains opium to the fluid ounce without a written order of the purchaser, the Circuit Court of Appeals, Fifth Circuit, held, Nelson v. United States, 298 Federal Reporter 93, that it was not necessary that the indictment negative that the paregoric was sold for medicinal purposes, and that it was for the defendant claiming exemption under section 6 to prove that he came within its provisions by showing that he had the written order required or that the preparation which he sold was intended by him to be used as medicine.

SUFFICIENCY OF CHARGE UNDER HARRISON ACT

The Circuit Court of Appeals, Seventh Circuit, holds, McIntosh v. United States, 1 Fed. (2nd) 427, that a charge, under a videlicet, under section 1 of the Harrison Act that defendant, without being registered, sold morphine sulphate, is supported by proof of a sale of morphine hydrochloride, there being no suggestion that the defendant was embarrassed in any way by the alleged variance, and the offense under the law being the same whether the defendant sold morphine sulphate or morphine hydrochloride.

REGISTRATION UNDER HARRISON ACT

The Circuit Court of Appeals, Eighth Circuit, holds, Weare v. United States, 1 Fed. (2nd) 617, that a person who sells or gives away opium or its derivatives, though only in a single instance, is a person who must register under section 1 of the Harrison Act, since the section does not say "carry on the business of" etc. Cases dealing with section 8, which relates to the possession of the drugs mentioned in the act, were held not in point in a case under section 1.

TUBERCULOSIS FROM INHALING GAS IN COKE PLANT HELD NOT AN ACCIDENT

The Virginia Supreme Court of Appeals holds Clinchfield Carbocoal Corp. v. Kiser, 124 S. E. 271, that an employee engaged in scraping out offtake pipes in a coke plant, through which pipes gas was discharged, and who was made sick by exposure to the gas, suffering nose bleeds and subsequently contracting tuberculosis, did not suffer injury from an accident within Virginia's Workmen's Compensation Act.

COMMENCEMENT OF MEDICAL TREATMENT PERIOD

The Indiana Appellate Court holds, Millspaugh & Irish Co. v. Lunte, 144 N. E. 147, that the legal rights of the employee and the corresponding duties of the employer, under section 25 of the Indiana Workmen's Compensation Act, providing for treatment, when necessary, for an additional period not exceeding thirty days after the first thirty day period, became enforceable when the injury has developed so that it may be diagnosed with reasonable certainty. Where the nature and extent of the injury, femoral hernia, was not ascertained until nearly a month after it occurred, it was held that the thirty day period during which the employer was liable for medical expense did not begin to run until that date.

SUNSTROKE TO TEAM DRIVER HELD COMPENSABLE

The Indiana Appellate Court holds, Townsend & Freeman Co. v. Taggart, 144 N. E. 556, that a sunstroke may be an accident within the Workmen's Compensation Act, and if the employment of a workman at the time he received a sunstroke was such as would expose him to a hazard beyond that of the general public then the disability resulting from the sunstroke will be regarded as due to an accident arising out of the employment. The driver of a team and wagon on a graveled highway on a very hot day was held to be exposed to a hazard beyond that of the general public and his disability resulting from a sunstroke was compensable as due to an accident arising out of his employment.

DEATH FROM INJURY RESULTING IN BLOOD POISON

The Iowa Supreme Court holds, Knowlton v. Preferred Accident Ins. Co., 199 N. W. 1014, that where an assured suffers an injury which results in blood poison, and the blood poison results in death, the proximate cause of death is the injury and not the blood poison.

ENTRAPMENT IN PRESCRIBING MORPHINE TO ADDICT DETECTIVE HELD NOT SHOWN

In a prosecution for furnishing morphine in violation of the Harrison Act it appeared that during nine months accused, a practicing physician, had given 108 morphine addicts a total of 4,095 prescriptions, calling for 79,592 grains of morphine. The Circuit Court of Appeals holds, Simmons v. United States, 300 Fed. 321, that, in view of the volume of the defendant's business of this type, the fact that the prescriptions on which conviction was had were given to an addict who was in the pay of the government and acting as a detective did not constitute the case one of forbidden entrapment. It was also held that the fact that defendant required his patients to bring a certificate from a health officer or some physician that they were afflicted with incurable disease, as required by the Tennessee statute, 1919, c. 105, and board of health regulations thereunder, did not constitute exculpatory good faith, the state law provision being in conflict with the Harrison Act.

PHYSICIANS DO NOT GUARANTEE SUCCESSFUL TREATMENT

The New Jersey Supreme Court holds, Grimaldi v. Heeglio, (decided June 15, 1925, not yet reported) that a patient cannot recover in an action for malpractice solely because the treatment given has been unsuccessful, but must show actual negligence by the defendant and that physicians are not guarantors of the success of their treatment unless they specifically make themselves such. The defendant in this case was a visiting physician at the Muhlenberg Hospital, Plainfield. The plaintiff was treated at the hospital under defendant's direction for a broken wrist. In some manner a wound upon the patient's arm became infected, resulting in suffering and the loss of use of the arm. The court, affirming judgment for the defendant, pointed out that infection may come from a variety of causes, and all a physician can do is to assist nature in throwing out the poison, and said: "It does not necessarily follow, however, that some one is responsible for this condition and must respond in damages for his suffering and reduced earning power. The skill and care that a physician is required to give his patient is that ordinarily possessed and exercised by others in his profession."

This decision is in accord with that by the same court in Smith v. Corrigan, 126 Atl. 680, noted in Medical Journal for June 17th, p. 796.

Some Causes of Ageing

MALFORD W. THEWLIS, M.D.

New York

What are the physiological processes which bring about the condition known to us as senility?

In recent years many physicians have emphasized the importance of the endocrine glands. Lorand and Horsley believed the thyroid gland to be an important factor. It is true that a lack of activity of the thyroid gland produces changes which are similar to those of old age. In cases of thyroid deficiencies, the skin becomes dry and wrinkled, the hair, eyelashes, eyebrows and beard thin. There is muscular weakness, sensitiveness to cold, and, as Brissaud says, "the entire body seems to be asleep." These changes are akin to those of senility, but this is no proof that the thyroid gland is a constant cause of senile changes. In fact, very often, in old age, we find a normal thyroid as well as other normal endocrine glands. We assume that normal senile changes affect the endocrine glands and that these disturbances are a result of old age rather than a cause of it. The importance of the gonads in relation to old age has been greatly exaggerated and there is no evidence to substantiate the use of gonad extracts and the opinions of the best medical minds are that these glands have little to do with the production of senility. Rejuvenation by means of gland transplantation has been generally discredited.

Metchnikoff maintained that old age was a result of toxemia, caused by syphilis, alcohol and bacteria in the colon. He believed that the putrefactive bacteria in the large intestines produced indol, skatol and phenol, which caused degenerative changes in the cells of the body. With sour milk and cultures of the Bacillus bulgaricus he hoped to check the process by destroying these bacteria. Sir Arbuthnot Lane (1) believed that chronic toxemia from the intestines was the cause of many senile degenerative changes. Undoubtedly, autointoxication from this source produces abnormal conditions.

Emile Demange (2) believed that senile changes were due "to a change in the quantity and quality of the interstitial nutritive material due to changes in the circulation, and this is due to atheroma and arteriosclerosis." He thought that, as a result of diminished calibre of the arteries, the nutrition to the parts was diminished. R. Thoma (3) wrote "the ceaseless activity of the heart and bloodvessels gradually weakens the elastic fibres of the vessels, as would happen in a piece of rubber which is expanded and contracted with ceaseless regularity. The loss of tone thus occasioned permits a dilatation of the vessels, the circulation is slackened partly through the dilatation and partly through the lessened contractility of the vessels and the nutrition of the organism is impaired."

Arteriosclerosis has long been looked upon as a cause of senility. However, arteriosclerosis in middle life due to lead poisoning or syphilis is not followed by changes characteristic of old age. There are many old people who do not have arteriosclerosis and it is safe to say that arterial sclerosis does not cause normal old age. According to Sir Humphrey Rolleston (4) arteriosclerosis is not constant in a considerable degree in old people and cannot be regarded as the cause of the degenerative changes in old age.

Ophülz (5) demonstrated that in many instances old age seemed to retard arteriosclerosis. Rolleston in commenting on Cazali's saying "man is as old as his arteries" says "the adventures of the man are a better index than the state of his arteries."

Much has been said about the results of increased blood pressure. It is a fact that arterial hypertension and arteriosclerosis may not necessarily coexist and we know of no reason why long continued high blood pressure should result in arteriosclerosis. We often find a generalized arteriosclerosis without a history of previous high blood pressure.

Essential hypertension is the term applied to high blood pressure without known cause. There are many people who have an increased blood pressure for years without accident and without resulting arterial changes or even kidney disease. Sir Clifford Allbutt (6) recognized the independence of the conditions and considered arteriosclerosis a degenerative process quite apart from hypertension. We cannot say that high blood pressure will cause kidney or heart disease because we have many examples of patients who never have these diseases. Moreover, we cannot say that a kidney disease is the cause of high blood pressure because so many patients suffering from Bright's disease never have high blood pressure. No doubt in many instances of long continued increased blood pressure, the kidneys and heart finally become affected; even in these cases we

Copyright, 1925, by A. R. Elliott Publishing Company.

cannot infer that the condition is due to increased blood pressure because it is possible that the same factors which cause the kidney and heart disease produce arterial hypertension.

MacCallum (7) concludes that elevated blood pressure acting alone produces little or no change.

The causes of arterial hypertension and arteriosclerosis may be numerous. Syphilis, lead poisoning, infectious diseases, disorders of metabolism and focal infection are important factors.

The theory that high blood pressure is due to kidney disease and a result of increased force spent to drive the blood through the diseased organ, has been discredited. In searching for pressor substances which cause an abnormal contraction of arterioles, and which cause an arteriolar spasm, it has been found that there are few soluble pressor substances. They are protein in nature and may be bacterial, metabolic, cellular or intestinal in origin. Dale and Dixon described the pressor action of amines such as isoamylamine, p-hydroxyphenylethylamine and phenylamine which were the result of putrefaction of protein.

Major and Stephenson (8) possibly have thrown a light on a new phase of the study of essential hypertension. They have shown that at least one normal metabolite is a pressor substance. They found that urea, creatin, creatinine and uric acid are without effect on blood pressure, but that guanidin bases have a pressor action to a marked degree. Several of the guanidin bases have this pressor effect. Methyl guanidin and dimethyl guanidin are normal end products of protein metabolism. As pointed out in the *Journal of Laboratory and Clinical Medicine* (9) the guanidin bases produce the symptoms characteristic of essential hypertension, uremia and eclampsia.

Obesity does not necessarily cause increased blood pressure; many patients suffering from elevated blood pressure are thin. We may find many old patients with low blood pressure and children who have a high pressure. Overweight is not always due to overeating; it may be due to metabolic disturbances. However, some patients who have elevated blood pressure improve when their weight is reduced.

The suprarenal gland has been thought by many to be a cause of elevated blood pressure since adrenalin is said to bring about a similar change. There is nothing to substantiate this theory and while the thyroid and other glands may do harm in individual cases they are not to be looked upon as a cause of hypertension or arteriosclerosis.

Excitement and worry are probably important factors in the cause of increased blood pressure. Excessive protein food may have a great deal to do with the condition by causing protein putrefaction in the intestines. Tea, coffee, tobacco and alcohol probably have little to do with the production of elevated blood pressure or arteriosclerosis. The problems of blood pressure and arteriosclerosis are not yet solved.

For a long time it has been supposed that cancer was a disease of civilization, due to overeating, overdrinking, lack of vitamines and to intestinal toxemia. Other diseases such as Bright's disease might possibly have been included with cancer. E. M. Hudson (10) has shown that we have been in error regarding the mortality of cancer. He has made an exhaustive study of the statistics and concludes that cancer is not on the increase; that in three thousand five hundred years we have only reached a point where eighty-six persons in one hundred thousand suffer from this disease. The proportion is small and there is no reason to fear the increase of cancer. Hudson believes that cancer is not a disease of civilization. He shows that cancer is on the increase up to the age of puberty, when its mortality is highest; after that time it gradually diminishes until we reach the last years of life, that is old age, when the disease actually declines.

I. L. Nascher (11) discussing the causes of ageing, stated that, in his opinion, there may be a progressive evolution in cell life; that at one stage of this evolution the cells were most perfectly adapted to their surroundings and their available nutrition; that later, fewer and imperfect cells were formed, and that finally the cells were so imperfect and so poorly fitted for the conditions under which they existed, that they either did not reproduce or else the organs which they formed could not perform their functions. Nascher further states that the most important factor in the life of the cell is its nutrition, which is derived from the constituents of the blood. "Impairment of the blood, either through the presence of abnormal constitutents or some alteration in quantity or quality of the normal constituents, affects not only those cells which derive nutriment from those impaired constituents or assimilate the toxic material. These cells are weakened, their activities are impaired, and they reproduce defective cells."

Rolleston (12) probably presents the most plausible theory in his book, which has been referred to. He states that the process of ageing of the cells is just as much a part of their development or life cycle as are their earlier and progressive stages. He believes that there is a more or less definite cycle during which cells multiply and after which they cease to do so. "The atrophy or hypoplasia of the organs is due to diminution of the proliferation of the constituent cells. The cells of the complex organism depend for their duration of life not so much on an inborn store of vitality as on metabolic changes in the colloids which in their turn are modified or controlled by extrinsic factors of various kinds."

Carrel and Ebeling (13) point out that the serum of an adult animal restrains the proliferation in vitro of homologous fibroblasts and that its inhibitory power increases progressively as the age of the animal advances. It was evident that the action of serum on homologous fibroblasts was not due to one inhibiting substance only, but rather to the combined action of two substances, one activating and the other inhibitory. In further experiments (14) these scientists show that the growth inhibiting substances are always more pronounced than the activating substances. The activating substances are thermolabile and are probably of the same nature as the growth activating substances contained in embryonic tissue juice and leucocytic extracts or secretions and may be considered as a product of gland

and leucocytic activities. "It may be supposed, therefore, that the enhanced restraining action of serum in old age is caused by a decrease of the activating substances, or by an increase of the inhibiting substances, or by both." (Carrel and Ebeling). These authors conclude, under the conditions of their experiments, as follows:

"1. The inhibiting action on homologous fibroblasts of the heated serum of a young animal increases relatively more than that of an old animal. After it has been heated, the inhibiting action of the serum of the old animals is still greater than that of the young animal.

2. The CO_2 precipitate obtained from the serum of a young animal definitely increases the proliferative activity of homologous fibroblasts, while the CO_2 precipitates of the serum of an old animal has practically no activating power. After the removal of the CO_2 precipitate, the inhibiting action of the serum of young animals is increased, while that of old animals is not modified.

3. The increased inhibiting action of serum on homologous fibroblasts in old age is partly due to the disappearance of the growth activating substances and to the enhanced activity of the growth inhibiting principles."

Furthermore, Carrel and Ebeling (15) show that egg white mixed with egg yolk and bouillon are not utilized by fibroblasts for multiplication. This fact renders more plausible the hypothesis advanced previously that for proliferation the fibroblasts require some nitrogenous substances elaborated by other cells, which are present in embryonic tissue juices.

We doubt if we can ever discover means of greatly lengthening life. There are many factors at play in the production of premature senility, such as an abnormal mode of living, and the excitement and worry of modern life. Normal old age seems to be a mystery as far as its actual cause is concerned. There seems to be a law of Nature which brings about old age just as it brings birth in a given length of time and puberty at another. If Rolleston is right, there is a more or less definite cycle during which cells multiply and after which they cease to do so. It seems to be the best explanation we have of the cause of normal old age. As for the causes of abnormal old age, to repeat, numerous factors must be considered.

How Soon Should Nasal Deformities, Due to Abscess of the Septum, Be Corrected by Transplantation of Bone?

WILLIAM WESLEY CARTER, A.M., M.D., F.A.C.S.

New York

In selecting a subject for a clinical paper I am frequently influenced by the communications which I receive from my confrères asking my opinion in regard to some particular case. These men, as a rule, are wideawake and well informed, and all are conscientious and solicitous in their attitude towards their patients. I reason that if men of such distinction need advice upon any subject, one cannot go far wrong in assuming that an open discussion of the points in question will serve a useful purpose by answering the unasked questions of many others. I trust that in trying to do this I may not add to the number of unwarranted communications which so clutter up medical literature.

Abscesses of the nasal septum are due to the introduction of pyogenic organisms between the layers of the mucoperichondrium. They are practically always due to traumatism, either accidental injury in which the nose may have been fractured, or infection may have followed some operation on the nose, usually the submucous operation for deflected septum. The number of deformities following the latter operation are occurring with increasing frequency and a note of warning should be sounded and surgeons should be urged to improve their technic and increase their precautions against infection.

All of the deformities following the submucous operation, however, are by no means due to infection; many are due to lack of skill on the part of the operator, or defective technic. Here the upper edge of the septum, or keystone of the nasal arch, is displaced from its normal position between the lateral cartilages and the nasal arch becomes established on a lower plane, constituting a saddleback deformity. In these cases the deformity is noted immediately after the operation. When this accident occurs the operator should anticipate the development of a deformity and should insert a bone transplant from the rib immediately. It is futile for the surgeon to try to undo the mischief by inserting pieces of car-

Fig. 1 Fig. 2 Fig. 3 Fig. 4

Figs. 1 and 2.—Deformity due to abscess of the septum following traumatic injury to the nose in early life.
Figs 3 and 4.—After correction of deformity by transplantation of bone and cartilage.

tilage removed from the septum, for these will have no fixed support and will gravitate into the submucous sac and deformity will result. What is indispensable here is a rafter of bone fixed to the frontal bone at the nasal spine and extending down under the soft tissues of the dorsum of the nose. It is unnecessary to say that the above situation should be carefully differentiated from abscess of the septum.

Abscess of the septum presents features peculiar to this locality, and these peculiarities should be kept well in mind by the rhinologist who treats the condition and by the plastic surgeon who corrects the deformity which always follows. The pus may burrow beneath the mucoperichondrium to such an extent that the latter is dissected on both sides from the entire septum.

A large abscess will frequently reach from the cribriform plate to the base of the vomer. In these cases the pus has been in contact for some time with the bone and cartilage of the septum and destruction of both of these tissues is more or less complete. Dead cartilage, as a rule, disappears gradually under a process of molecular disintegration; while the dead bone is cast off as a sequestrum. Now the sac between the two layers of the mucoperichondrium is quite a commodious pouch, and when it is infected and filled with dead bone and cartilage, some time must elapse, even under the most approved treatment, before its surgical cleanliness can be assured, and bone transplantation for the correction of the deformity cannot be considered under any other circumstances, otherwise failure is absolutely certain to follow.

Undoubtedly live bacteria lie dormant in tissues surrounding the old abscess cavity for a considerable period of time and we must be reasonably certain that these are no longer present before operating, for the transplantation of bone and cartilage, which is recognized as the only means by which these deformities can be satisfactorily corrected, is an operation of extreme delicacy and all factors bearing upon its successful conclusion should be carefully considered.

The patient's general health should be good. A Wassermann test should always be made; this is very important, for the saddleback nose is one of the characteristic manifestations of tertiary syphilis, and the testimony of patients upon this subject is notoriously unreliable and should be checked up by the scientific test. A Wassermann positive patient is not a good subject for bone transplantation under ordinary circumstances, and should always be subjected to a thorough course of treatment before operation.

As is very well known, there are some syphilitic patients who cannot be made Wassermann negative, even though the most approved treatment is continued over a long period. Several of these cases have come under my observation and because of impelling circumstances have insisted upon having the deformity corrected by bone transplantation. In all such cases I have placed the burden of responsibility for the success of the operation upon the patient. Most of these patients were plus two after prolonged treatment, and much to my surprise and gratification the results have been excellent, the transplant behaving exactly as in a successful nonspecific implantation.

A minimum of six weeks should be allowed to elapse following an abscess of the septum before an attempt should be made to correct the deformity by bone and cartilage transplantation. There may be indications for waiting much longer and they should always be obeyed. There is a considerable advantage in operating before cicatricial contraction following the abscess has reached its maximum. There is a phase in every case where the infection has disappeared and the cicatricial contraction has not progressed very far, which, if we knew how to detect it, would be the ideal time to operate; this, however, cannot be predicted with certainty, and we must err on the safe side and always give the patient an ample margin of time to recover from the abscess infection.

In the deformities following abscess of the septum, bone and cartilage transplants, introduced from within the nose in the manner originally described by me, afford an ideal means for restoring the symmetry of the organ. There is no scar, and when conjoined bone and cartilage are used, the transplant being taken at the junction of the rib with the costal cartilage, as originally suggested by me several years ago, not only is the resiliency of the nasal tip preserved, but the normal anatomical relations of the nose are restored.

The correction of the deformity is permanent, and noses restored in this manner resist traumatism as well as before the injury occurred.

Postoperative Parotitis

EMIL NOVAK, M.D.
and L. A. ANTUPIT, M.D.
Baltimore, Md.

While comparatively rare, the occurrence of parotitis as a postoperative complication may be fraught with much danger to the patient. It is therefore surprising to note how little attention the condition has received in the literature. Sporadic reports of cases have been made from time to time since the development of modern abdominal surgery. As far back as 1886 Stephen Paget (1 and 2) called attention to the importance of the complication, which he associated more particularly with gynecological surgery. This was not unnatural, for two reasons. In the first place it had long been known that epidemic parotitis or mumps was occasionally associated with metastases to the ovary. When parotid inflammation occurred following operations upon the pelvic organs, it was not unnatural to suspect that one was dealing with a reflex or sympathetic process emanating from the ovary. Secondly, it must be remembered that a large proportion of the operations performed in the early days of abdominal surgery were of a gynecological nature, so that it was not surprising that the possibility of an ovarian causation loomed large in Paget's mind. It need scarcely be said that no evidence can be advanced to support such a theory as Paget's, and indeed, it can be at once disproved by the now well known fact that parotitis is often seen after operations not in any way dealing with the pelvic organs. For that matter, many cases have been observed in males.

Our incentive for the present brief paper was furnished by the study of three cases of postoperative parotitis which appeared to illustrate rather well the types commonly recognized, particularly from the standpoint of prognostic significance.

CASE HISTORIES

Case I.—Mrs. I. U., aged twenty-three, was operated upon April 14, 1923, for chronic pelvic inflammatory disease and chronic appendicitis. Her general condition was excellent. Recovery was satisfactory, except for a slight stitch infection. On the tenth day there appeared a considerable swelling of the left parotid gland, with some tenderness and slight fever (99.5°). The swelling became quite marked, and there was some increase in the fever, up to 101°. The gland was incised, but no pus was obtained, and the swelling gradually receded, being entirely gone in about two weeks after its appearance.

Case II.—Mrs. J. S., aged thirty-eight, was operated upon August 27, 1921, for gallstones and chronic appendicitis, the operation consisting of cholecystectomy and appendectomy. On the fifth day the left parotid gland, and two days later the right, began to swell. There was a gradual increase in both the swelling and the discomfort, and the fever ranged between 100° and 103°. Fluctuation developed within a few days and both sides were incised and drained. The discharge persisted for many days, and the swelling and induration diminished very slowly, the entire process requiring at least three weeks.

Case III.—Mrs. H. J., aged forty-nine, had suffered from severe digestive disturbance for several years and for two years there had been persistent vomiting. The patient had become extremely emaciated and weak. She had lost all her teeth and the mouth was quite dry. A definite mass could be felt in the epigastrium and the x ray confirmed the clinical impression of advanced cancer, with obstruction of the pylorus. A palliative gastroenterostomy was considered advisable, and was performed on October 28, 1924, the operation being a comparatively easy one. The patient's condition was relatively good for about seven days and the vomiting ceased entirely. Mouth washes had been used and much fluid given by both mouth and rectum. On the seventh day a swelling of the right parotid gland was noted, and this increased quite rapidly. The left gland became enlarged a few days after the right, and soon the enlargement became huge, especially because of the surrounding cellulitis, extending far down the neck. At this time the region above the neck was like a truncated pyramid, with the base at the shoulders.

The patient became more and more septic, in spite of the fact that both sides had been freely incised and drained. A moderate amount of pus was obtained at the first incision and the drainage continued very freely. Cultures of the pus showed staphylococcus aureus. Great sloughs were brought away through the wound. On one occasion, when I entered the patient's room as she was being dressed, I thought a sponge was being drawn out of the wound, so large was the sloughing mass being removed. In spite of the usual supportive and eliminating treatment, the patient became more and more septic and debilitated, and death took place on November 18, 1921, twenty-one days after the operation, and fourteen days after the appearance of the parotitis.

ETIOLOGY.

Although Paget's theory, mentioned above, is generally abandoned, there is no unanimity of opinion as yet concerning the cause of this complication. It may follow any form of abdominal operation. Some believe it to be most common after operations upon the gastrointestinal canal, and especially for cancer of the stomach. Others, again, state that it is more frequently noted following pelvic operations. There are some who believe that the most important predisposing factor is a bruising of the parotid gland by roughness on the part of the anesthetist. While such injury to the gland tissue, if it actually does occur, might well lower its resistance, this factor can scarcely be of importance in the immediate cause of the condition. Other theories have from time to time been suggested, such as that of Dyball (3) (1904), to the effect that the development of the parotitis is due to the selective action upon the gland of some unknown toxin which is liberated during operation. This theory is of course purely speculative.

The two explanations which alone seem worthy

of serious consideration are, first, that the parotitis is due to a hematogenous infection, second, that it is due to infection ascending along Stenson's duct. Theoretically, the first mentioned route for infection appears to be a plausible one, and certainly the actual one in cases of the pyemic type, where there is a general dissemination of pus foci. However, this is not the common clinical picture encountered, for often the general condition is good and there is rarely any evidence of metastatic abscesses in other tissues. Furthermore, a hematogenous infection would be more likely to be a localized one, rather than the diffuse process so commonly seen. Finally, rare as pathological studies have been, it appears to have been shown that the usual form of the lesion is characterized by periductal rather than perivascular infiltration, (4) thus again arguing against the hematogenous mechanism.

By far the most plausible explanation of the cause of postoperative parotitis is that which appears to have been first suggested by Bunts (5) in 1904. He observed that the complication was most common in patients who had poor teeth, gingivitis or other oral infections, and insalivation. Excessive dryness of the mouth is common after general anesthesia, and especially in those cases where atropine has been administered beforehand. Postoperatively great dryness of the mouth and poor oral hygiene are also noted in patients in whom fluids and nonmoistened foods are given by rectum instead of by mouth, as after certain stomach operations.

Infection of Stenson's duct is especially apt to occur if the secretion of the parotid gland is greatly diminished, especially where other predisposing oral conditions are present. Inflammatory occlusion of the duct may occur, facilitating the extension of the infection into the substance of the gland. Hyperemia, with edema, soon occurs, with rapid involvement of the whole gland, often continuing to suppuration, with perhaps extensive sloughing. Without going into details, it may be stated that such an explanation fits in better with known facts as to incidence, symptomatology and physical findings better than any other. When we speak of infection along Stenson's duct we must bear in mind the possibility that this is transmitted along the lymphatics rather than by direct extension along the mucosa. The exact mechanism is of course not known.

There has been some discussion as to why the parotid gland is involved in preference to the submaxillary and sublingual. Low (6) has explained this as due to the fact that the mucin containing secretions of the submaxillary and sublingual glands are strongly bactericidal, while the serous parotid secretion is not. Furthermore, the openings of the submaxillary and sublingual ducts are within the alveolar border, covered by the tongue and kept clean by the movements of the latter. Stenson's duct, on the other hand, opens outside the alveolar border and is in intimate relation with the molar teeth, which are more often carious than any others.

CLINICAL FEATURES.

Various types of acute postoperative nonepidemic parotitis have been described, but there seems to be no advantage in recognizing more than two, viz., the nonsuppurative and the suppurative. The first of these is less frequent than the second, and also very much less serious. It makes itself evident usually on from the third to the eighth day after operation. Pain and swelling appear over one or the other parotid gland, and there is usually only a moderate fever. The swelling gradually increases and may become very great, giving a picture much like that of mumps, especially when the gland of the opposite side becomes involved, as not infrequently occurs within a few days. The skin over the affected glands may become red and tense, but fluctuation is absent. The general condition of the patient is usually quite good, although there is apt to be considerable local discomfort, especially difficulty in swallowing. Within a few days the swelling begins to abate, the fever to diminish, and the patient's discomfort to lessen. Some induration may, however, persist for a good many days.

The suppurative type presents a very different picture. It may be noted in patients whose preoperative condition had been excellent. In these the onset is similar to that of the nonsuppurative type, though usually more severe, and perhaps accompanied by a chill. After a few days the swelling may become enormous, the fever high, the skin red, shiny and edematous, while the leucocytosis is apt to be quite high. The lesion may remain unilateral or may become bilateral. Fluctuation may appear, but the decision to incise should not be deferred for this, as the pus may be deeply seated beneath the dense parotid fascia, so that fluctuation may not be noted until very late or perhaps not at all. The constitutional symptoms may become severe, with septic fever, rapid pulse, and pronounced prostration.

If, as is unfortunately often the case, the preoperative condition of the patient was poor, as in Case III, the picture is a far graver one. Especially does this seem to be true in the cancer cachexias, for, as we have seen, the complication is perhaps most common after operations for stomach cancer. The patient in such cases soon becomes profoundly septic, the pulse becoming more and more rapid and of poorer quality, while the fever shows the usual septicemic fluctuation. Great as is the swelling of the gland, it appears even larger because of the surrounding cellulitis, involving a great portion of the neck. In extreme cases the patient's head forms the top of a pyramid, with its broad base at or just above the shoulders. Incision does not always halt the process. When the resistance is low and the injection relatively virulent, the entire gland may slough, and the cellulitis apparently spread, with no sign of regenerative activity. The patient may be overwhelmed within a comparatively short time, but more commonly lingers along for a good many days before succumbing.

PROGNOSIS.

Speaking generally, the mortality of this complication has been put at about thirty per cent. From what has been said, however, it is evident that the prognosis is dependent very largely upon the previous condition of the patient, as well as the intensity of the process. Since the latter is no doubt largely dependent upon the patient's resistance, it will be seen that, after all, it is this personal factor of the patient's previous condition which is most important

in determining the result. Death is uncommon when the patient's general condition has been excellent, while, on the other hand, it is generally to be expected in the violent suppurating and sloughing types, occurring in debilitated and perhaps cachectic individuals.

PREVENTION AND TREATMENT.

From what has been said of the etiology, certain measures looking to the prevention of parotitis would seem rational. Unfortunately the complication is not sufficiently frequent to call forth constant routine prophylactic vigilance. It would seem wise, however, to enforce oral hygiene in all patients upon whom abdominal operations are to be performed, especially if the patient's general condition is very poor. Cleansing of the teeth and the use of antiseptic mouth washes are of course important. After operation, in addition to such measures, it would seem important to prevent excessive dryness of the mouth. Plenty of fluids are to be given if there is no contraindication. The use of chewing gum has been advocated to keep up a free flow of saliva.

If pus forms, or if its presence is suspected, the gland should be incised. As already stated, the surgeon should not wait for fluctuation. Multiple incisions may be necessary over suspiciously soft or prominent areas. Through the incision, if pus is not encountered, one may explore the gland in various directions with a forceps. The usual precautions so necessary in operations on the parotid region should of course be observed, and need not be discussed here.

Priapism: The Report of a Case of Forty-Five Days' Duration, Due to a Lesion of the Conus*

GEORGE WILSON, M.D.
and J. P. MAUS, M.D.
Philadelphia

Priapism is a pathological, persistent erection of the penis, not accompanied by sexual desire and usually painful. It does not often respond to medication and yet may subside spontaneously.

Hinman (1) could find 170 cases reported up to 1914. He found it simple and practical to classify cases of priapism in two groups,—those due to nervous causes and those due to local mechanical conditions. In the 170 recorded cases there were thirty-five due to lesions of the nervous system. Five cases secondary to nasal polyps were cured with one exception by their removal.

The duration of the attacks varied from two days to two years. Over sixty-five per cent. of the cases attributed to mechanical causes lasted from twenty to sixty days. Eighty-five per cent. of the nervous cases lasted less than ten days although early death occurred in fifty per cent. of them.

The character of the erection was stated in sixty-three of the histories and in forty-three of them (seventy per cent.) the corpora cavernosa alone were involved; thirty-eight of these cases were in the mechanical group. In ten nervous cases the whole penis was involved, while in only ten of the cases due to mechanical conditions was a complete erection observed.

Pain was always present. Sexual desire was lost in 107 cases and in three cases of the nervous group a temporary increased desire was noted. The following report is of interest:

*From the Department of Neurology of the School of Medicine of the University of Pennsylvania.

Case.—A colored man thirty-nine years old, a harnessmaker with a negative family history, came to us complaining of a persistent erection of his penis. He had gonorrhea at the age of twenty and gonorrhea and a chancre at twenty-one. He always used tobacco and alcohol to excess. He served in the United States Army for fourteen years, two of them being in the Philippines. When he was in the army he had an erection while he was in the saddle; the erection persisted as long as he remained mounted but subsided as soon as he dismounted. One year ago he had an erection of twelve hours' duration; he was sexually excited at the time, but failed to have his desires satisfied. During this attack a physician applied local medication and gave him pills. Four months ago he had a third attack of priapism which also lasted twelve hours. In the last two attacks the erections were not painful but were associated with a slight burning sensation in the rectum.

Present illness.—The man awoke on October 20, 1923, at 2:00 a. m. with an erection; this being a rather common occurrence, he paid no particular attention to it, turned over and went to sleep. The erection persisted the next day and that night he tried with three different women to cause a return of the penis to its resting state but his continued efforts were without the consummation he desired. He succeeded in having ejaculations although they were not associated with the ordinary pleasurable feelings. As the days went on without relief he sought the advice of two physicians and finally consulted an osteopath. The physicians did no good.

The osteopath made things worse by his manipulation of the vertebræ and penis. The patient stated that he had been able to void a normal amount of urine and he complained of a severe burning pain in the rectum.

Examination.—The facies were anxious but no evidence of acute pain was present. The penis was in a state of persistent erection, both the corpora cavernosa and corpus spongiosum were involved. The urethra, prostate and seminal vesicles were normal. Some difficulty in voiding was present but the bladder could be completely emptied and a catheter was passed without difficulty. Pupils, cranial nerves, nose and throat and muscular power in all extremities were normal. All the deep reflexes were present and active but the right patellar and achilles reflexes were not nearly so active as the left. Abdominal, cremasteric and plantar reflexes were normal. Prostatic smear, blood, urine, spinal fluid and x ray of the vertebral column were normal.

Clinical course and outcome.—On the thirty-first day of the priapism the man was given spinal anesthesia which was successful as far as the anesthesia was concerned but it had no effect on the erection. On the thirty-fifth day at the Naval Hospital, League Island, Philadelphia, the man was etherized and this produced no effect on the priapism. An incision was then made through the skin at the right lateral margin near the base of the penis and was continued through the corpus cavernosum, septum and into the left corpus. A considerable amount of dark blood and several small clots were evacuated; this had no effect on the state of the penis. Two days later under ether a second incision was made at the left lateral margin opposite that made previously and rubber tissue drainage was inserted through the wounds. Five days after the second operation the penis was semiflaccid distal to the incision but was spastic proximally. The erection slowly subsided so that at the end of forty-five days it approached the normal although it was not entirely flaccid. One year later the penis was flaccid and sexual desire and power had not returned.

Comment.—The case which we have cited above probably falls into the group of nervous cases although the evidence to back up this assertion might be considered flimsy. The man had distinct irregularity of the patellar and achilles reflexes, both of these reflexes being greater on the left side. This would mean a lesion, probably meningitic, extending from the second lumbar to the third sacral segments on the right side. It is well known that early in such conditions (which are usually syphilitic) satyriasis may occur and also persistent erections without sexual desire. In such a case persistent erection due originally to a nervous origin might later be converted into one dependent upon a mechanical state.

It is known that the centres in the spinal cord governing erection are localized in the conus although L. R. Muller (2) believes that the centres for erection are not in the cord at all but are in the sympathetic ganglia of the pelvis. The centres for ejaculation are separate and distinct and above those for erection.

We have recently seen a clear cut example that the centres for ejaculation and erection are separate. A man who received a severe injury to the lower part of his spinal cord developed a flaccid, crural paraplegia, loss of control of the sphincters and loss of sexual power. He gradually recovered, in order, power in the lower extremities, control of the bowels and bladder and then the power of erection, but it was some weeks before he was able to bring about an ejaculation.

In the case which we have reported we believe that there was present a localized meningomyelitic affection of the lower part of the spinal cord involving the reflex arcs of the right patellar and achilles reflexes and going a little lower and involving the centres for erection. After a time the nervous cause for erection was perpetuated by a mechanical disturbance. This was relieved by operation and the penis returned to a quiet state.

Tonsillectomy in Rural Practice

L. A. HULBERT, M.D.,
Springville, N. Y.

It is the prevailing opinion today, especially among specialists in diseases of the throat, that tonsillectomy is a major operation and should only be done in a hospital under ideal conditions. This idea is also instilled in the minds of many rural practitioners. The result is that many diseased tonsils in both adults and children living in rural districts never come to operation. The time, and more especially the money, are not available for their hospitalization. Distance from the medical centres and the specialists is too great. The ultimate outcome is evident. These same patients later present themselves complaining of vague muscular and joint pains, occasionally with acutely swollen and tender joints, general malaise, and shortness of breath on slight exertion, the victims of the end results of a long standing focus of infection.

There is no question that the same fundamental principles of asepsis and care should form the basis of tonsil operations as of any other surgical procedure. Yet it is evident that the technic can be so simplified as to permit its being carried out in the home or in the office of the rural physician, with as satisfactory results as are obtained in the hospital—thus bringing this service within the reach of many who need it.

This review is of one hundred consecutive tonsil operations taken from rural practice, covering a

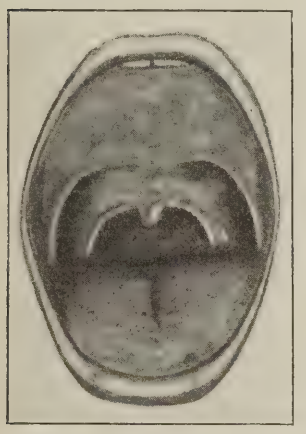

Fig. 2.—Tonsillectomy in a child, under general anesthesia, one and one half years after operation.

period of two years. It includes both children and adults, varying in age from two and one half years to fifty-four years. The children, sixty-six in number, were operated upon under general ether anesthesia; the adults, thirty-four in number, under local anesthesia. An arbitrary age of fifteen years was taken as the dividing line between children and adults. All operations were performed outside of a hospital and with the assistance of only one other person. Not one case terminated fatally. All were without complications except one, in a child, in which pleurisy developed on the third day following general anesthesia, lasting one week and terminating in complete recovery.

All cases were of the chronic hypertrophic type, both the fibrous and lymphoid variety. Many of the tonsils were enormously enlarged, touching in the midline, cryptic, and filled with a cheesy material; others so necrotic that only a shell remained. Some were situated very superficially, others deeply imbedded. The first group, when removed, left a shallow fossa, the latter, large well defined pillars. Those cases giving a long history of repeated attacks of tonsillitis presented a very fibrous tonsil, firmly adherent to the anterior and posterior pillars offering difficulty in dissection. Adenoid hypertrophy in the nasopharynx was found in the majority of the cases in children. Some were reoperative cases, the tonsil having first been removed when the patient was a child, the recurring tonsil becoming diseased and causing symptoms in a similar manner to the original tonsil.

Careful histories were taken of the cases, with special reference to any pathological condition in the chest and any tendency to abnormal bleeding. This was checked up with physical examination and coagulation time, using the simple glass slide method. A coagulation time of over ten minutes was considered abnormal. Existing colds, bronchitis, and other disorders of the respiratory organs, were treated for a short period, if necessary. Care was taken not to operate in a case during any phase of the acute stage of an attack of tonsillitis.

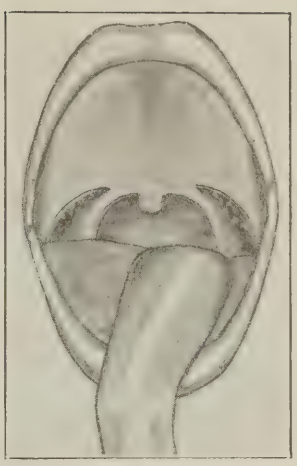

Fig. 3.—Tonsillectomy in a child five years old, one week after operation, showing slight amount of exudate in superior part of fossa.

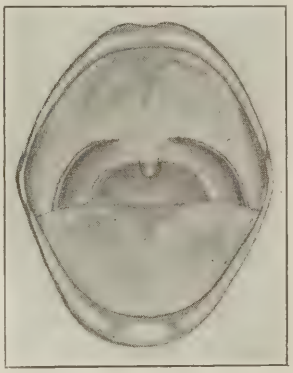

Fig. 4.—The resulting state of a tonsillectomy in a child, showing the condition prevailing one year after operation.

In sixty per cent. of the cases the patients gave as their chief complaint frequent attacks of tonsillitis, sore throat, and quinsy, varying in duration from a few days to eight weeks. In the children this symptom was associated with mouth breathing, restlessness at night, and a "general run down condition." In this group, especially among the children, frequent winter and spring colds were common, complicated by middle ear infection. This tendency was more marked in those patients having an abundance of adenoid tissue. Eight and two tenths per cent. of the patients gave colds as their chief complaint; 3.5 per cent. of the adults complained of rheumatism, and one patient complained of "localized neuritis." Nine per cent. complained of tiredness and a lack of usual vigor. Chorea existed in one child.

The children were given general ether anesthesia, administered by a nurse assistant, and continued by a Sorensen pressure suction apparatus, the nurse thus being free to prepare herself to assist in holding the tongue depressor during operation. The only preoperative preparation was an enema the night before the operation and nothing by mouth the morning of the operation. For the adults, a local anesthetic was used, which was prepared in the office by dissolving one Metz "B" tablet (novocaine 0.1 gm., suprarenin 0.00025 gm.) in seven cubic centimetres of double distilled Ringer's solution and this sterilized. This gives a 1.5 per cent. novocaine solution and 0.002 mininum of 1:1000 adrenalin solution to each cubic centimetre. No preoperative preparation was necessary.

The anesthetic was infiltrated posterolateral to the tonsil, using a fine hypodermic needle on a 5 c. c. all glass syringe fitted with a three and a half inch extension to permit of deep infiltration. The infiltration was started at the superior pole of the tonsil well back from the margin of the anterior pillar in an effort to get behind the tonsil and place the anesthetic in the region of the tonsillar plexus of nerves, anesthetizing the superior pole of the tonsil, the soft palate and palatine arches. The needle was next introduced through the anterior pillar at its midpoint, and carried behind the tonsil infiltrating the capsule and lateral surface of the tonsil. The third point of infiltration is deep beneath the lower pole of the tonsil and on a line with the angle of the jaw. An effort is made to infiltrate behind the field of operation rather than in it. Postoperative pain is thus minimized.

A 26 gauge 3.5 cm. needle was used, which allowed of painless introduction, and deep infiltration. The

injections were made very slowly, using little force. First the right and then the left tonsil was infiltrated, allowing ten to twenty minutes for its effect. Toxic symptoms were rarely noticed.

TECHNIC

First the right then the left tonsil is enucleated. The patient is instructed to open the mouth and breathe in a panting manner. There is little trouble from gagging if the patient will continue to breathe properly. The tongue is then gently depressed along its lateral margin and retracted medially and forward. This gives full exposure of the field of operation, and especially brings into view the lower pole of the tonsil which often lies far down along the base of the tongue, and which may otherwise be left. The right tonsil is seized with a Ballenger tenaculum along its long axis, pulled medially and rotated forward, thus placing the anterior pillar under some tension. The primary incision is then made along the margin of the anterior pillar at a point where the mucous membrane is reflected onto the surface of the tonsil. This incision is carried through to the glistening white tonsillar capsule. With a Hurd dissector the tonsil is gently shelled from its fossa. The dissection is first carried along the anterior pillar well down along the base of the tongue; then the superior pole is freed and the tonsil gently dissected free from the posterior pillar. This completed, the tonsil is entirely free from the pillars and hangs pendulous in its fossa. It is then snared with an Eve wire snare. A gauze plug is immediately inserted into the fossa and held temporarily. This procedure controls any bleeding which may occur. Care is taken not to leave the fossa until rendered clean and dry. An electric headlight furnishes the most satisfactory light.

The operation can be done quickly, causes little discomfort to the patient, and is entirely painless. The minimum amount of trauma and no resulting shock combine to make a quick and comfortable convalescence.

Figs. 2, 3 and 4 are drawings made of throats operated upon in this series of cases. They show distinct well defined pillars, a uniform throat, and a clean well healed fossa.

AFTERCARE

In the ether cases the patients were allowed to react in the office and then returned to their home two or three hours after the operation. In the cases where local anesthesia was used, the patients returned home immediately, with instructions to remain quiet. All patients were permitted cold food on the day of operation, and a regular diet thereafter. A cleansing gargle was used every two or three hours consisting of salt and soda of each one half teaspoonful to half a glass of warm water. Healing was complete in from one to two weeks. The throats remained sore for about one week, but there was little or no discomfort after the first twenty-four or thirty-six hours. Convalescence was more rapid in the children than in the adults. Difficulty in swallowing was relieved by allowing the following powder to dissolve on the tongue: Acetylsalicylic acid, two and a half grains, acetanilide, half a grain.

In only three of the cases in this series was there any degree of postoperative hemorrhage. All were of mild type, and in the cases where operation was performed under a local anesthetic, two were due to dislodgment of large clots by coughing; the other because of a mild inflammatory condition of the surrounding tissues. Both were arrested by direct pressure.

RESULTS

Forty-eight per cent. of the patients have been cured of all symptoms complained of at the time of operation; forty-nine per cent. were very much improved, and three per cent. unimproved. The greatest percentage of cure was in the child groups; sixty per cent. as compared with thirty-four per cent. in the adult group. This is explained by bearing in mind the fact that the chief complaints among the children were the immediate result of their diseased tonsils and adenoids, while in the adult group the complaints were remote results or complicating conditions following long standing tonsillar infection, many of which were permanent or had become chronic. Ninety-five per cent. of the children showed a remarkable gain in general health following the operation. A gain of ten to twenty pounds in weight was not uncommon, beginning a few weeks after operation, and steadily continuing. Along with this was a gradual increase in physical vigor and mental alertness. Children previously backward in school soon came up to the average for their age. The adults were slower in their general gain, yet progressive; associated conditions—neuritis, rheumatism and general malaise—were cured or much improved.

Considered surgically the majority of the cases were satisfactory, throats were uniform, pillars prominent, and fossa clean and smooth. A small percentage showed a less well defined posterior pillar and more or less contraction of the tonsillar fossa. This was noticed in those cases where there were large superficially situated tonsils. A few of the patients complained of some soreness and irritation following operation, especially the reoperative cases.

Since operation the incidence of most infectious diseases has been less during the two year period of observation. This holds especially for the child group, though an increased resistance is noted among the adults. This conclusion is based upon a comparison with similar children who have not been operated upon, as they present themselves at the office for treatment.

Tonsillitis and sore throat were decreased eighty per cent. in the tonsillectomized children. The tendency to frequent winter colds was greatly reduced, especially in those having had enlarged adenoids. In this same group there was a decrease in ear infection. The occurrence of measles was not affected. The tendency to diphtheria infection was reduced.

CONCLUSIONS

1. Tonsil operations should receive the same care in technic as other surgical procedures.

2. The technic can be so simplified as to permit of its being carried out in the office of the rural physician, thus bringing this service within the reach of many who need it.

3. Results are satisfactory.

Reconstruction of Ankylosed Joints

*With Special Reference to the Aftertreatment**

WILLIS C. CAMPBELL, M.D.

Memphis, Tenn.

Surgery, until recently, has offered no relief to those afflicted with ankylosed joints, though efforts have been made for about one hundred years to reestablish motion by operative procedures. This has been, in part, due to the limited experience of the surgeon, who could not induce many to submit when the chances of success were so slight, and as the number operated by any one surgeon has been small, and usually followed by recurrence, there have been few advocates. Many problems have been elucidated by animal experiments in medicine and surgery, but in bony ankylosis of joints such measures are of absolutely no value, for it would be difficult to produce ankylosis in animals and impossible to obtain intelligent cooperation in the reestablishment of active motion which is positively essential. The early operators devoted their attention towards the prevention of fusion between the bony surfaces, with little, if any, consideration to the synchronous physiological action of all of the component parts, as the muscles, nerve stimuli, ligaments, etc., which constitute the function complex of a normal joint.

Motion in ankylosed joints may be acquired by wide excision of bone, but too often at the expense of stability. A stiff joint in a good position is by far more satisfactory, unless function can be secured with strength, durability, and without pain or tenderness. The operative technic to reconstruct a joint is known as arthroplasty, a well defined surgical procedure, and should not be confused with excision, the induction of pseudoarthrosis. Unfortunately, however, this has already occurred as noted in the recent symposium before the International Society of Surgery. An analysis of one report clearly shows that ninety-two of 180 mobilizing operations were mere excisions and not true arthroplasties.

The scope of the procedure increases with the experience of the surgeon, though care must be exercised in the selection of cases. The following pathological conditions encountered in ankylosed joints decrease the chance of success, or actually contraindicate surgical measures:

1. Tuberculosis. In no case should a joint be entered for the purpose of mobilization when tuberculosis was the causative agent in the production of ankylosis. Undoubtedly, it might be possible to obtain excellent results in some instances, but the probability of lighting up a latent tuberculous process is well known and should be sufficient warning against surgical measures.

2. In those in whom a destructive osteitis, in early life, has obliterated the epiphyses a materially shortened extremity is encountered and mobilization would not be of sufficient advantage to justify the means.

3. Extensive scar tissue, binding the skin to the bone, requires preliminary plastic procedures.

4. Extreme muscular atrophy, with reorganization of bone structure, as is seen when a bony ankylosis has existed over a long period of time and the medulla has become continuous through the joint, as from the ankle to the knee—in such an instance, sufficient base would not be found to reconstruct a functional joint, besides the open medullary canal might be a factor to be considered. The muscular apparatus would also be extremely atrophic and its restoration difficult.

5. Old dense eburnated bone, when found for a considerable distance on both sides of the joint, is not favorable soil for reproduction of a movable joint. Such a condition is usually caused by an extensive virulent osteomyelitis, the result of which is a low grade bone tissue, bearing the same relation to normal bone that scar tissue does to normal soft tissues. In fact, healthy, spongy bone should compose the articular surfaces of the new joint, consequently the chance of success is very slight when the structure of the bone has been transformed for one or more inches beyond the joint line.

6. All evidence of an acute infection must have subsided before the institution of operative measures. This is a well known surgical principle.

7. All evidence of osteoporosis or bone atrophy must have disappeared, with restoration of normal bone before the procedure should be considered.

In fact, surgical operations for the purpose of mobilization are rarely, if ever, permissible except when ankylosis has been caused by two conditions, 1, trauma, 2, infectious arthritis, caused by staphylococcus, streptococcus, pneumococcus, gonococcus, and other organisms. These organisms erode and disintegrate the cartilages and superficial bone of the articulations, unless the infection is in the shaft, when there is an extensive osteomyelitis and not a localized arthritis.

No attempt will be made to collaborate the literature, but merely to relate facts obtained from personal experience in 120 arthroplasties. However, reference will be made without reservation to my former publications.

There are two types of ankylosis, bony and fibrous, the latter less frequently encountered than the former. As the surgical procedures are the same in both, neither is of any practical significance. Extra articular ankylosis or restoration of motion from contractures of the soft parts is a separate equation and irrelevant to this subject.

In the reconstruction of an ankylosed joint, due consideration must be given to four important factors: 1, the soft tissues; 2, the bones; 3, interposition of material between the joint surfaces; 4, aftertreatment.

The plan of attack must be intelligently considered in each case so that when operation is completed there may be sufficient laxity to permit mobility without tension. The joint cavity must be closed by at least one substantial layer of tissue, and, if possible,

*Read before joint meeting of Kansas City Clinical Society and Southwestern Medical Society, October 15, 1924, Kansas City, Mo.

as many as normal. This requires a plastic adjustment of tendons, ligaments and fasciæ. Care must also be taken to avoid nerve injury at the time of operation and thereafter by mechanical action of the reconstructed joint.

In the first cases of a series of one hundred and ten,

Fig. 1.—Simple apparatus for instituting active and passive motion on the eighth day after arthroplasty of the knee.

the technic as described by others was followed, by minutely duplicating the joint surfaces, but after considerable experience, beset with a high percentage of failures, it was discovered that simplicity was a real asset, and that we should strive to reproduce function, and not necessarily anatomical detail—for instance—in the knee joint, as will be later demonstrated one large condyle on the femur and one shallow concave tuberosity of the tibia will acquire a hinge joint which meets all requirements.

The necessity of interposing tissue between the joint surface, as a substitute for the synovial membrane and to prevent bony fusion, has been demonstrated in all of the joints with the exception of the temporomaxillary and possibly the wrist joint. After employing animal membranes, and in a limited number no material, it has been concluded that free fascia lata is the choice. A histological review of normal fascia later was made by O. W. Hyman, of the University of Tennessee, from a specimen removed at operation. He demonstrated that the arrangement of fibres on the under surface was more regular, smoother than the upper layers, and had the same appearance as tendon tissue. In consequence, in transplanting, a sheet of sufficient dimensions is excised, and reversed, so as to place the smooth glistening surface without and thereby accomplish easy gliding motion. The pedunculated fascial flap, advocated by Murphy, has been discontinued except in special conditions, as it is difficult to obtain flap without extensive dissection of the soft parts, with increased local postoperative reaction. And, unless by some plastic rearrangement as defined in technic on the elbow, it is doubtful that viability is permanent, with the result that a free transplant is produced at a disadvantage.

The indications for arthroplasty are rare in those joints whose action may be compensated by motion in adjacent articulations, as the shoulder and ankle. The joints which respond most favorably are, in the order of their chance of success, the elbow, the jaw, the knee, and the hip. The technic of the operative procedure differs in individual joints as does the anatomy and function requiring a special description of the procedure in each.

THE ELBOW

Arthroplasty of the elbow was described in *Annals of Surgery* (May, 1923, vol. XXVII, No. 5), with the exception of recent modifications, as follows:

"An incision is made, from six to eight inches in length, on the posterior aspect of the arm and forearm, just external to the midline, beginning above, about the middle of the humerus and ending about two or three inches below the elbow joint. Skin, superficial and deep fascia are incised without separation, the deep fascia is dissected laterally, about one inch. This brings the broad aponeurosis of the triceps into view. This structure is dissected from above downward, making a long tongue attached to the tip of the olecranon process below. A further incision in the midline passes through the muscular fibres of the triceps and periosteum to the humerus over the lower half. A periosteal elevator is now used to strip the periosteum from the lower third of the humerus. Scar tissue, callous and loose bony particles are removed. If dislocation exists, reduction is then accomplished without difficulty with periosteal elevator, scoop or any blunt instrument.

There is no structure of consequence in the line of incision, no danger of vessel and nerve injury if one remains close to the bone; however, if the ulnar nerve is exposed it can be isolated and anchored into a position of safety. About one half to one inch is removed from the lower extremity of the humerus, which is remodeled into a surface convex from before backward, no attempt being made to reproduce trochlea or capitellum. About one half inch of bone is removed from the tip of the olecranon process. All scar tissue is dissected from the sigmoid cavity. With a sharp chisel the surface is removed to healthy spongy bone. Fusion between the radius and ulna is severed and sufficient bone resected. The surface of the head of the radius must be made the same level as the coronoid process, a rasp and file render smooth all surfaces. Rotation of the radius depends

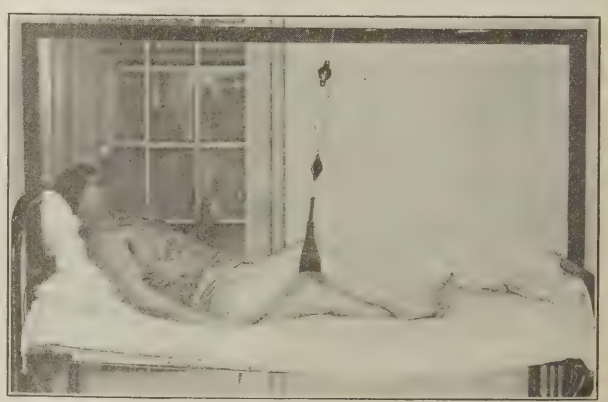

Fig. 2.—Simple sling and pulley apparatus for continuing active and passive motion at the home of the patient during convalescence.

solely on the integrity of the upper radioulnar joint, the radiohumeral playing no part. The periosteum and triceps muscle are dissected into a double flap, which is stitched to the anterior capsule, thus separating the raw bony surfaces by a living mass of tissue with abundant blood supply and no risk of

pressure necrosis. In those cases where the radiohumeral articulation is normal with bony ankylosis between ulna and humerus, the radiohumeral joint is not destroyed, but a hemiarthroplasty is employed between the humerus and the ulna. In such cases it is not always possible to obtain sufficient posterior

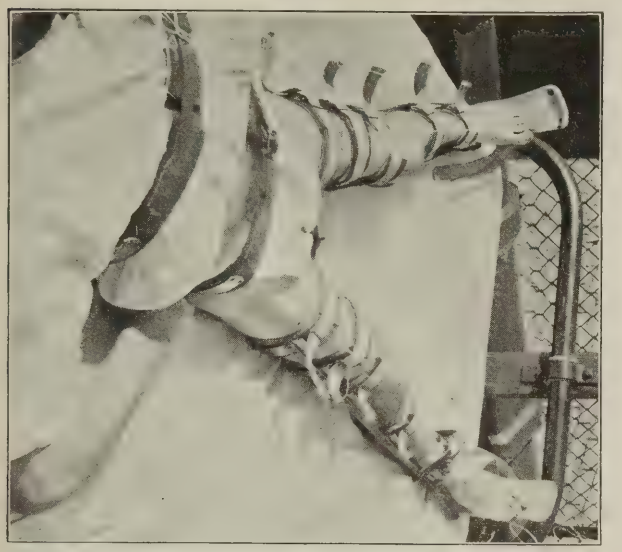

FIG. 3.—Apparatus in aftertreatment of arthroplasty of the hip, holding pelvis firm to insure hip motion and prevent compensatory spinal motion.

flap in lieu of which the aponeurotic broad tongue from the triceps is placed between the surfaces. This structure is also employed when, for any reason, the posterior flap can not be secured. The capsule of the joint is stitched to the posterior aspect of the triceps muscle and deep fascia, thus closing off the new joint—the wound is then closed in layers with catgut and dermal for the skin. In some instances when there have been atrophic muscles, not supplying sufficient tissue to cover the articular surfaces, it has been necessary to employ a free fascia lata transplant.

THE JAW

In the temporomaxillary an L shaped incision, as described by Murphy, is made, and, as emphasized by Henderson, motion is secured by excising sufficient bone, about one half an inch, after which the condyle and joint cavity are made with chisel and small rasp. It is unnecessary to interpose any material. In extraarticular bony ankylosis, with solid bony fusion of the alveolar process, usually the sequelæ of noma, the incision is made in the oral cavity with wide bony excision, or until free motion is secured. The latter type is not a true arthroplasty but is mentioned in this connection as the clinical aspects are the same, and also the aftertreatment. It was necessary to do a tracheotomy in one instance, after which the operation was completed with ease. A tracheotomy tube should always be placed on the instrument table.

THE KNEE JOINT

In remodeling the knee joint no routine technic is applicable but must be modified to accommodate the following conditions: (As described in an address (1) before the Orthopedic Section of the New York Academy of Medicine, January, 1923.)

1. Position, extension, flexion, flexion and external rotation and valgus.

2. Distribution of ankylosis. a. Fusion of patella and femur with tibiofemoral articulation—apparently normal. b. Tibiofemoral fusion with freely movable patella. c. Hemiankylosis—one condyle and its articulating tuberosity fused with the other half of the joint apparently intact. d. Panankylosis—complete bony fusion of patella, femur and tibia, by far the most frequent occurrence.

The operative technic in complete bony ankylosis with extension will be described in detail, after which such modifications as variations may require.

OPERATIVE TECHNIC IN EXTENSION

The skin incision is an inverted U. Beginning just below the inner tuberosity and passing about one inch above the patella, terminating at the outer tuberosity, a straight incision of four or five inches is made at right angles, about one inch external and parallel with the quadriceps tendon, differing from the Putti approach in that the vertical portion is not directly over the tendon—a distinct advantage. In a number of cases recently a long internal incision, parallel with the quadriceps and patella, has been sufficient. After cutting through fat and fascia, dissection is made over the quadriceps tendon, which structure is lengthened by the common Z plastic method, leaving the outer half attached to the patella below, which will later be of value in closing. With a large osteotome the union between the patella and femur is severed. The incision is then carried downward to

Fig. 4

Fig. 5

FIG. 4.—Normal motion six weeks after arthroplasty of the temporomaxillary joint.

FIG. 5.—Solid bony ankylosis of the left temporomaxillary joint, five years' duration.

the bones on both sides, as far as the upper extremity of the tibia. The tibiofemoral union is completely severed, no attempt being made to forcibly flex, even in fibrous cases, until this is accomplished, for fractures of the lower extremity of the femur are easily sustained, and may seriously complicate. The knee is then fully flexed giving free access to the raw bony surfaces of the tibia and femur. In a normal individual, who has no lateral play in the sound knee (previously noted), from one half to one inch of bone is removed from the femur. The surface is then made convex from before backward and on the same plane from side to side, so that the femur presents one large condyle. The intercondylar notch is obliterated in the process. As small an amount of the upper extremity of the tibia as possible is excised

in order to reach healthy spongy bone. With a large gouge this surface is made slightly concave from before backward—one large shallow cavity for articulation with the one condyle of the femur—two points of articulation instead of the normal four. No attempt is made to reproduce spine of the tibia or intercondylar notch of the femur, for there will be no crucial ligaments to prevent lateral displacement which may easily occur, bringing irregular surfaces together with obvious mechanical damage, when motion is instituted. The raw surfaces are next approximated and the alignment of the entire extremity tested. If varus or valgus more bone is removed from each surface until a perfectly straight hinge is formed. Special care should be taken not to produce valgus regardless of the position of the normal limb. Future weight bearing must be direct and in a straight line. The knee is next hyperextended, when there should be at least thirty degrees. If this can not be attained more bone should be removed except in individuals with very lax joints or atrophic musculature, when ten or fifteen degrees hyperextension is sufficient.

Our attention is next directed to the patella—the posterior surface is removed to a very thin layer, just sufficient to be consistent with tensile strength. The lateral margins are trimmed for one fourth of an inch so as to allow the tendinous fibres to fold backward along the edge of the posterior surface. A large rasp renders all surfaces smooth. All recesses are carefully searched with the aid of a magnifying glass, and every particle of loose bone removed. Just below the patella and on the posterior aspect of the patella tendon will be found a mass of fat, and, at times, a layer of synovial membrane, which is severed at the junction with the tibia and dissected from below upward into a flap with a broad pedicle which is stitched with number one catgut, to the margin of the tendinous fibres, above described, along the inner and outer edge of the posterior surface. This is an important step, for in those cases in which ankylosis recurs, adhesion begins between patella and femur and is the most difficult problem encountered in restoring mobility.

Free fascia lata is transplanted from the outer aspect of the opposite thigh, taking a very large sheet, four or five inches in width by eight or ten inches in length, turning the deep surface out, as one of the functions of this membrane is the free easy play of the muscles beneath. This sheet of fascia is placed over four or five inches of the anterior aspect of the femur and attached muscles, being anchored above to the deep fibres of the muscles, it then passes over the condyle of the femur and is stitched to the posterior capsule, as high as possible, after which it drops downward along the posterior capsule and finally forward to the anterior surface of the tibia—all free edges are stitched with continuous chromic catgut well over the margins of the joint. The joint remains flexed sixty degrees for closure, as the capsule may be contracted and if closed in extension free flexion would not be permitted, thus defeating the purpose of the operation. The inner portion can always be united as the vastus internus extends lower and there is more resiliency in the soft parts on the inner side. For this reason the quadriceps tendon is severed above, through the outer half, and below, through the inner half, so that the outer half is attached to the patella. If the edges of the capsule can not be brought together in flexion, a flap of fascia or muscle may bridge the defect, as it is absolutely essential to restore a closed intact mechanical joint. The quadriceps tendon, fascia and skin are sutured

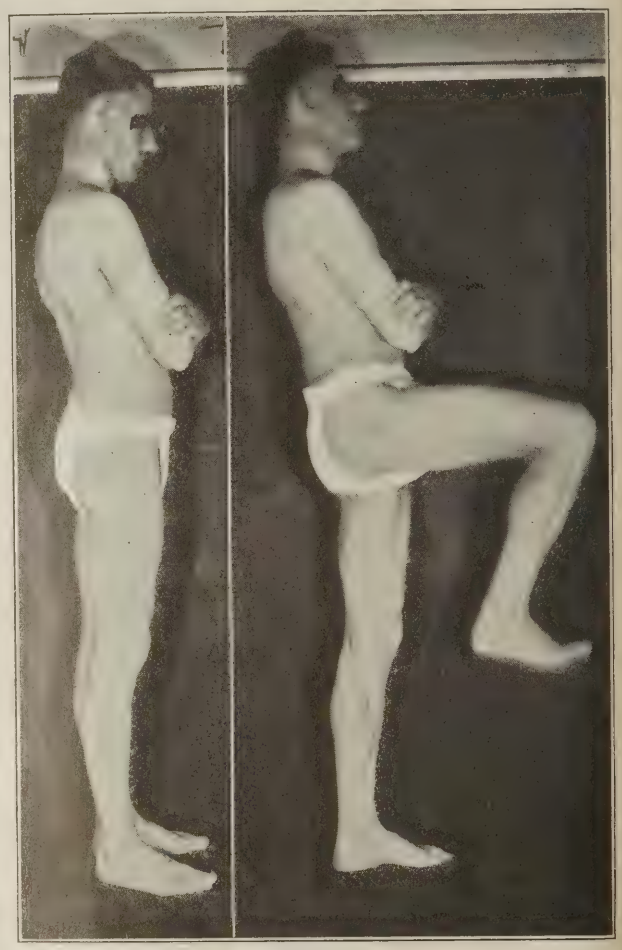

Fig. 6.—Showing extension and 90° flexion of right hip nine years after arthroplasty.

in routine manner, using chromic catgut for deep structures and dermal suture for skin.

Technic in Complete Ankylosis in Flexion

When ankylosis occurs in flexion the anterior structures are redundant after removal of sufficient amount of bone, however, severence of the posterior capsule may be necessary, though stripping of the periosteum above and below, for one or two inches, has been found sufficient. The quadriceps tendon can be retracted to the inner side without dividing, which is an obvious asset. The greater the degree of flexion, the larger the amount of bone excised.

Technic in Fusion of Patella and Femur

In fusion between patella and femur, with an apparently normal tibiofemoral articulation, the position is always extension or possibly very slight flexion. The patella is treated as above described, and in addition a broad sheet of fascia lata, from the outer aspect, folded beneath the patella and quadriceps, being retained in situ by stitching to the vastus internus, the deep surface of the fold facing the patella and quadriceps. This is not a pedunculated

strip, but a living viable fold. When scar tissue invades, a free fascial transplant is taken from the opposite thigh. If the capsule space is not sufficient to allow flexion, plastic adjustment is required.

TIBIOFEMORAL FUSION WITH MOVABLE PATELLA

When tibiofemoral fusion occurs, with a freely movable patella, the incision should be U shaped across the patella tendon. The patella tendon is lengthened by Z plastic method, after which the new joint is remodeled as described above. This condition is not a sequela of acute infectious arthritis, but usually the result of a virulent infectious osteomyelitis, with direct bone infection across the joint space, the interior portion of the joint being protected and walled off by inflammatory exudate, a counterpart of which is so often seen in the abdominal cavity.

TECHNIC OF HEMIARTHROPLASTY

Occasionally a considerable portion of the joint surface is intact and may be conserved. This may frequently be accomplished in the elbow and shoulder, described in a recent article as hemiarthroplasty. After remodeling the affected portion of a pedicle flap is usually quite sufficient.

There are several points to be elucidated:

1. The amount of bone to be removed depends upon the position of the limb, the contracture of the soft parts and the musculature of the individual. Roughly speaking, from one to one and one half inches, though possibly as much as two inches has been removed. A satisfactory degree of hyperextension may be secured.

2. Inequality. Shortening has never been of practical disadvantage nor a question of consequence, if a movable joint is attained. If over two inches a stiff joint, in an improved position, would be more satisfactory.

3. Instability. An unwarranted fear if one remains within the bounds of reason and does not remove too much bone from the pedestal—the tibia, and if normal healthy bone, free of osteoporosis, constitute the articular surfaces.

HIP

In the hip the typical Kocher U incision is made in most cases, occasionally a modification of the Smith-Peterson incision by continuing the lower end backward. The greater trochanter is chiseled at the base giving access to the head and neck. It is often impossible to determine the articular line. With a curved wood carver's chisel, as used by Dr. Baer, the bony fusion is cut at the junction between the neck and ilium. With Murphy instruments a new acetabulum and head are reconstructed. If a true ball and socket joint is to be reproduced there must be sufficient neck of the femur available. A large strip of free fascia lata is transplanted from the outer aspect of the same thigh, just above the knee joint, with which the head is entirely covered and a fold is reflexed over the acetabulum. The pedunculated fascial flap in some instances may be employed.

ANKLE

The indications are rare in the ankle joint. If malposition exists astragalectomy will give a very useful member. As there are only two arthroplasties of the ankle in this series an expression of opinion is unwarranted.

WRIST JOINT

A long posterior incision is made over the midline. The carpus is sculptured into one convex condyle and the radius and the ulna into one receiving cavity. No material is interposed and function is instituted early. If the joint is in dorsiflexion with normal rotation of the forearm arthroplasty is not indicated, but in all malpositions the procedure is worthy of consideration.

SHOULDER JOINT

Arthroplasties are rarely, if ever, indicated in the shoulder joint, when there is compensatory motion of the scapula. In many the bony fusion may be severed, after which rotation of the head will bring normal cartilage into articulation with the glenoid cavity. Should no cartilage be found on the head of the bone a pedunculated flap may be easily obtained.

AFTERTREATMENT

The aftertreatment has been standardized for each joint and must be strictly enforced or failure is inevitable. Apparatus adapted to the requirements of each joint is applied as soon as the operation is completed. In the elbow a simple right angle splint is sufficient—and at the end of ten days active and passive motion is instituted under the direct control of the patient, by a system of overhead pulleys, and an attachment to the head of the bed. A Balkan frame is often used, or a simple wooden bar. No reaction is induced as the movements are made with the normal hand of the patient, who remains within the range of painless motion, which is gradually increased. The splint can be removed at the end of three weeks, but active and passive motion continued until the maximum is secured.

In the jaw a wedge is placed between the teeth in full extension, being removed every hour for active motion, which is begun on the second day. At the end of a week the wedge is discarded. The teeth are cleaned and repaired as early as possible, as there are always extensive caries and oral sepsis. This will enable normal mastication of food which is a natural asset. No joint responds as rapidly as the jaw, complete range of motion being often acquired in a few weeks.

In the knee a Thomas splint with hinge is applied on the operating table, with continuous traction in extension. On the eighth or tenth day active and passive motion is begun by a system of pulleys under direct control of the patient, as in the elbow. The patient remains in bed for six weeks when splint is discontinued and walking is permitted with the use of crutches, but movements continued by overhead sling and pulley.

In the hip a plaster cast is applied, from the ankle to the nipple, in moderate abduction, with weight and pulley extension by adhesive attached to skin, ten to twenty pounds is sufficient to overcome muscle spasm and intraarticular pressure. An abduction hip splint with fixed traction may be used instead of the cast, the Bradford type preferably. On the tenth day the cast is bivalved to the hip joint and the same principle of active and passive motion given as in the knee and elbow. Walking is often permitted with crutches at the end of three weeks, usually much earlier than in the knee.

In the knee and hip the stamina of the bones as determined by the röntgenograms is most important, especially with reference to osteoporosis, or bone atrophy. If such a condition exists, which fortunately is rare, or is increasing, as may occur after any irritation of bone tissue, motion in the part must be guarded, or else the contour of the articular surfaces may become irregular. If weight is borne before structure of bone is of sufficient density there may be further damage, and the entire purpose of the procedure defeated. The joint space may become irregular and increased to such an extent that deformity, instability, or a flail joint is the result. However, when osteoporosis complicates, the restoration of bony structure to normal can always be accomplished by permitting weight and motion to be gradually increased, by adjusting a Thomas splint so as to receive the weight on the tuberosity of the ischium. As the röntgenogram demonstrates that the structure of bone approaches normal, there may be a synchronous increase in weight bearing until the normal is safely possible. There can be no arbitrary period for restoration of function, but as a rule a satisfactory range of motion is secured by the end of three months, which increases with the development of the inactive muscular system, reaching the maximum result by the end of two years.

As a compensation problem, disability is determined from the nature of the employment and the joint affected, in the individual case. In sedentary vocations, as stenographers, clerks, and others, three months is usually sufficient, and, in many instances, two months in the lower extremity, with the aid of crutches. In the upper extremity those acting in an executive capacity may return to their occupations within two or three weeks. In mechanics and laborers, total disability is indefinite and may require complete rehabilitation.

Physiotherapy is a most valuable adjunct and should be employed in every case when possible, but on account of the enormous expense, which many could not incur, the standard treatment for each joint was evolved, thus placing the procedure within the reach of the poorest ward patient.

Rarely it becomes necessary to use brisement forcé, but when indicated, gas oxygen is administered, and the range of motion increased only ten or twenty degrees. If above this point the reaction is severe and may delay treatment until stronger adhesions have formed with actual decrease in function.

It has been stated that fortitude and endurance to an abnormal degree are required, but this is untrue, as motion is not given to the point of excessive pain, which the patient soon learns to control. In early cases before the aftertreatment was standardized, many discontinued on account of pain incurred at the hands of the attendant, or physiotherapeutist, but in recent years there has been splendid cooperation on the part of practically every patient, with a marked increase in the percentage of excellent results.

An analysis of 110 arthroplasties was read before the Surgical Section of the American Medical Association in June, 1924, in which distribution as to joints was as follows:

Elbow, fourteen; jaw, six; hip, twenty-three; knee, fifty-nine; ankle, two; wrist, three; phalangeal, one; metatarsal, two.

As the technic in operative and aftertreatment has improved there has likewise been an elevation in the ratio of successful end results and at present the chance of success is estimated in the four joints, more adaptable to arthroplasty, as in the following tabulation:

Temporomaxillary, ninety per cent.; elbow, ninety per cent.; hip, single, sixty per cent.; knee, seventy-five per cent.

The röntgenogram of a reconstructed joint, after the lapse of sufficient time, demonstrates definite bone production about the margin of the articular surfaces, which has been mistaken for an active proliferative osteoarthritis, though it would hardly be possible to remodel so extensive an area of raw bone without inducing appreciable reaction by osteophytic formation about the margins of the joint surfaces. The argument that such changes are not commensurate with durability is hardly tenable, as the counterpart is found in many useful and apparently normal joints, the sequela of trauma or infection. In fact, those past fifty often present material evidence of osteoarthritis in the röntgenogram without a single subjective symptom.

It has been asserted by several surgeons that function has been secured within a few months with the gradual restoration of motion until by the end of one year or more there was recurrence of ankylosis. It has also been stated that when motion was secured the joints were weak, painful and subject to injury and strain. In order to determine the durability sixteen were personally examined, no evidence by correspondence, or otherwise, being considered. There were four elbows, three hips and nine knees, in which from three to ten years have elapsed since operation. All showed definite proliferative changes in the x ray as would be expected. There had been no retrograde change, but a gradual improvement in motion, muscular power and endurance. About seventy-five per cent. stated that the joint was subject to fatigue after less exertion than the normal joint but that efficient service was obtained. All were enthusiastic in the results as compared to their former condition.

CONCLUSIONS

1. There is a vast difference between arthroplasty and excision. The former is the reconstruction of a joint, the latter the induction of pseudoarthrosis.

2. Our efforts should be directed towards reproducing function and not mere anatomical detail, thus simplifying and standardizing operative technic.

3. Fear of removal of too much bone is unwarranted if one remains within the bounds of reason. Unstable joints are the results of atrophy and not excision of bone.

4. The röntgenograms, after several months, show extensive reactive proliferation about the margins of the articular surfaces, but not a true arthritis. Analogous conditions are found in apparently normal joints, as a result of trauma or infection.

5. The aftertreatment must be intelligently carried out, especially with reference to osteoporosis, or atrophic bone changes, which can be avoided by intensive physiotherapy and gradual weight bearing restricted by special apparatus.

The Mastoid Operation

A Discussion of the Results in One Hundred Cases

JOSEPH FRIEDMAN, M.D.
and SAMUEL GREENFIELD, M.D.
Brooklyn

(*Concluded from page* 206)

We cannot dwell at length upon all the important and interesting features that we have encountered, but a more detailed description of the interesting cases that occurred in our series will be found in a subsequent publication.

Much has been said and written of the mastoid operation. From the time of its early conception in the days of Ambrose Paré up to the present day, numerous modifications, variations and additions have been made rendering it a procedure as systematic, exact and precise as one finds in all the realms of surgery. For its recognized introduceion into the field of otology in 1868 we are indebted to Schwartzae, who also at that time enunciated the indications, principles and technical elements upon which are based the steps of the modern mastoid operation. The fundamental principles governing the original operation are not protean, for all the subsequent innovations are concerned mainly with the minor details of the procedure, the basic technical steps remaining essentially those of Schwartzae. Thus has been evolved over a period of years an operation which has definite indications; a technic which in its execution calls for a systematic orderly approach in the process of eradicating the disease; an ultimate aim to reach the outermost limits of the infectious process so that when the mastoid has been completely dissected we are assured that not the slightest vestige of diseased tissue has been permitted to remain.

In an acute mastoid abscess we are dealing with disease of the bone. The bony partitions that divide the mastoid into compartments are undergoing various stages of inflammation and necrosis. The compartments communicate with each other and are filled with pus, granulations and destructive microorganisms. The process is one of extension spreading at the periphery to the adjacent bone, originating from the region of the antrum. The disease is most advanced therefore about the antrum and from here in all directions to the outermost limits of the disease, the bone is undergoing all the intermediary stages of inflammation. It is impossible macroscopically to determine where diseased tissue ends and healthy tissue begins. It is therefore imperative that the operator not permit the feel of his curette to serve as his guide, in determining the extent of his operation. There is only one safe method. The mastoid must be cleaned out thoroughly, and this can only be accomplished by reaching the outermost confines of the mastoid cavity.

The mastoid process is a honeycombed affair. The cells extend in all directions, being bounded by definite structures which in most instances determine the area through which it is possible for the disease to become disseminated. The anterior limit of the mastoid is marked by the posterior canal wall, the horizontal semicircular canal and the zygoma. The upper limit is the tegmen antri and the floor of the middle cerebral fossa. Posteriorly is the lateral sinus and below is the mastoid tip. The area enclosed by these structures is filled in with cells of varying sizes, the bony partitions extending on to and being intimately connected with the bone covering these structures. For this reason the cells of the mastoid are divided into five groups: 1, an anterior set situated along the posterior canal wall, extending from the tip below to the attic; 2, suprasinus cells located above the sinus over the floor of the middle fossa, and also including the zygomatic cells in front; 3, sinus cells running along the sinus groove; 4, deep cells found between the sinus and the bulb, internal to the facial nerve; 5, the tip cells. Knowing therefore where these various cells are located and bearing in mind the fact that we can never be sure as to the exact limits of the disease, it should be the endeavor of the operator to map out structures which mark the limits of the mastoid and only then can we feel assured that no diseased tissue has been permitted to remain. The zygomatic region should be cleaned out thoroughly. As was first pointed out by Whiting (9), neglect in exenterating these cells is a common cause of failure of the mastoid to heal. The internal table over the floor of the middle fossa should be plainly seen. The groove between the knee of the sinus and the middle fossa must be worked out. The sinus plate should be visible throughout. The deep cells must be sought for and the tip cells opened up thoroughly, and the tip removed wherever necessary.

We operated upon a young man eighteen years of age, in whom we found a sclerotic mastoid. As usual we dissected the entire mastoid until we came upon what most men would have taken for healthy solid bone. But we were bent on seeing the sinus plate, and we worked back fully a quarter of an inch until we struck what appeared to be this structure. While smoothing off with a Richards curette it suddenly gave way and we broke through the bone and there was a sudden gush of pus. The patient had a large perisinus abscess. Had we been content with doing the ordinary antrotomy this would have been overlooked, and we believe that in this case there would have developed a complication.

The mastoid operation as we have practised it is identical with the technic taught us by Dr. Friesner at the Manhattan Eye, Ear and Throat Hospital, New York City. In all our cases we have been thorough. We have made every effort to reach the remotest recesses and we have followed up the disease to its outermost limits. In every instance there has been a clean and complete dissection of the mastoid process. We have paid special care not to expose structures unnecessarily.

It is not our intention to offer any startling additions to the technic of the mastoid operation. We wish to emphasize most strongly, however, the importance of a well developed systematic routine and the necessity of adhering to each and every step in that routine and so foster the most thorough and complete work.

Briefly the steps in the operation as we have performed it are as follows: 1, postauricular curvolinear incision a quarter inch behind the postauricular fold beginning just below the tip and extending to the upper attachment of the concha. This incision will do in the majority of cases; where there is a flat broad mastoid, especially with cells that reach beyond the sinus, the Whiting incision may be resorted to; 2, reflexion of soft parts and periosteum until the posterior and superior canal walls are visible. The entire mastoid should be uncovered and the tip well freed from the surrounding muscle tissue. We wish to caution against dislodging the membraneous canal more than is absolutely essential. Tearing the canal away from the bony attachment is likely to result later in an atresia of the auditory canal; 3, removal of a strip of cortex parallel to the posterior canal wall, beginning on a line with the roof of the bony meatus extending down to the tip. This is best done with the large gouge; 4, with a Spratt curette, preferably one of the medium size, a groove is made along the posterior canal wall; 5, the field of operation is then mapped out by biting off the cortex over the proposed area of operation. This is accomplished by the use of a large ronguer, beginning near the tip, for the sinus is situated deeper at this point. In using the ronguer it is safer to take small bites; 6, the original groove is now deepened and widened. This will usually result in the opening of the antrum. All the cells along the posterior canal wall are cleaned out thoroughly. In this locality the small Spratt or Richards curette may be used to advantage. A boring motion, working from above downward, using the upper limit of the mastoid as a fulcrum, always working parallel to the canal wall, will prove both efficacious and safe; 7, the cells over the middle fossa should be scraped and all overhang removed until the internal table is plainly visible. Continuing forward we proceed to the zygomatic area and clean out all the cells in this locality. In some instances this region is quite extensive and to be thorough will oftentimes bring us far beyond the meatus. Our work here must be exceedingly careful and gentle, for the dura is very easily exposed; 8, the cells in the groove between the middle fossa and the knee of the sinus are now attacked. These cells are often much diseased and it is absolutely essential that they be thoroughly excenterated. We have used the medium sized Spratt curette to great advantage in this region; 9, the sinus groove should now be freed of cells. This is best accomplished by using the large Richards curette employing strokes parallel to the sinus. The cells often extend well beyond the sinus and we must bite off overhang and curette repeatedly until all disease has been removed. The sinus plate should be visible along its entire extent. The deep cells situated between the sinus and the bulb internal to the facial nerve are best opened with a small Spratt curette; 10, the tip is then removed with a ronguer following the digastric muscle. In all adults we have removed the tip, in young children there is so little tip that we have permitted it to remain; 11, the posterior canal wall is lowered with a small ronguer and all bony edges are smoothed off with a large Richards curette; 12, the aditus is enlarged. The granulation tissue in the attic should not be disturbed. We have not curetted in this region; 13, the operation being completed, the mastoid cavity is irrigated with warm saline, the débris and loose shreds removed. The cavity is then swabbed with iodine. Iodoform gauze packing is used and the canal is cleaned and packed with plain gauze; 14, sutures are employed in adults, closing the upper half of the wound. Where there is exposure of the sinus and dura to any extent, and especially where there is disease of these structures, the wound is left widely open. In all children we have employed the same procedure as above. In subperiosteal cases sutures have not been used and the edematous soft parts have been thoroughly curetted; 15, dry dressings are applied externally.

In regard to the aftertreatment, in our cases we have followed the well known surgical principles governing the treatment of surgical wounds elsewhere. We are all agreed that the period of convalescence and recovery can be materially shortened by careful and well applied aftertreatment in mastoid wounds, and on the other hand this period can be prolonged for weeks and weeks, as a result of improper care and attention and the failure to bear in mind certain fundamental surgical factors which are peculiar to the healing of wounds of this kind.

As a result of the completed mastoid operation, there is created a bony cavity which in the process of repair and healing becomes filled in with newly formed tissue. This process of replacement of the defect must begin in the deepest part of the cavity and gradually make its way to the surface. Therefore until this takes place the superficial borders of the wound must be kept patent. Furthermore this attempt to keep the wound open insures free and easy exit of the secretions which invariably are infectious. The continual bathing in pus of newly formed granulation tissue is apt to infect it and so convert it into a foul smelling poorly nourished mass that cannot be utilized for reconstruction. The wound refuses to heal under these circumstances; the process of repair is impeded. It is therefore most essential that the dressings be changed often enough to accomplish this end.

The condition of the middle ear is also an important guiding consideration. It is certainly to be considered a poor result in which the mastoid wound heals and the middle ear remains moist with the persistence of a perforation in the drum membrane. It is therefore essential that posterior drainage be maintained as long as possible in these cases where the middle ear continues to discharge.

It is the minor details often that govern to a great extent the efficiency of our methods and it is to these that we wish to call special attention. The matter of dressings and when to do them is of paramount importance. In uncomplicated cases the first full dressing should be done on the fifth day. Outer dressings may be changed as often as becomes necessary. For the first week thereafter, we have advised

daily dressings and we have found as a result much cleaner wounds. After the twelfth day the patients are seen every other day. As soon as possib'e we dispense with the bandage and employ adhesive dressings instead. For some reason or other this change seems to have a most beneficial effect, be it psychic or otherwise, for it has been noted that healing seems to progress more rapidly.

At each dressing the canal should be swabbed with hydrogen peroxide and freed of all secretion, and thoroughly dried. A sterile piece of packing is then introduced very lightly. Haste, rough handling, or lack of care in its insertion may result in injury of the lining of the canal, thus breaking its continuity. With the presence of pus constant infection may thereby be introduced with subsequent external otitis localized or diffuse, a painful and most uncomfortable complication. Packing the canal tightly is unnecessary and may cause discomfort for hours after.

When granulations spring up overabundantly, they may be controlled with the silver stick. If they become unhealthy, the curette or scissors may be used to remove them. When the wounds are clean, in order to hasten the growth of granulation tissue, balsam of peru has proven very efficacious.

We hardly feel it necessary to emphasize the great importance of carrying out the strictest aseptic measures in the dressings of mastoid wounds. Success in obtaining rapid healing will depend largely upon the observance of this feature.

The complications of mastoid disease are numerous and result not only from the disease, but also from the performance of the operation itself. We are all agreed that some complications are unavoidable; while others may be justly attributed to faulty technic on the part of the operator.

In consideration of these complications we wish to enumerate the following as we have encountered them in our series: 1, death; there occurred one death in a child, aged two years, seven hours after the mastoid operation. The child was apparently normal; the operation ran off smoothly; no structures were injured; the child came out of the anesthetic in good condition. Death was sudden; the possible causes offered were embolism, shock, or a latent basilar meningitis; 2, sinus thrombosis. There occurred two cases of lateral sinus thrombosis, one discovered at the primary operation, and the other secondary; 3, meningitis, no cases; 4, facial paralysis, no cases; 5, erysipelas, we have encountered two cases, one was the socalled white erysipelas; 6, brain abscess, in one patient in whom we operated for a Gradenigo, complicating scarlet, we probed for a temporosphenoidal abscess, but failed to find pus. This patient had localizing symptoms. Four days after the mastoid operation she had a convulsion, and became comatose. After coming out of her coma, she had a distinct aphasia, with a partial hemiplegia of the corresponding side. The case was seen by Friesner, Strauss, and Elsberg, and all agreed upon the diagnosis. As was stated before, no pus was found and the patient made a complete recovery; 7, labyrinthitis, no cases; 8, infection of the tissues of the neck. In our series there occurred two cases of Bezolds mastoiditis, in both cases we counterdrained from below. In another patient, an adult aged forty-two, there occurred an extensive induration down the neck to below the clavicle. The entire area was tender and painful. We treated it expectantly. The induration disappeared completely without pus formation. Aside from the complications mentioned above there were no others that occurred in connection with our cases.

In the series of one hundred cases we have not had occasion to perform one secondary operation and we have attributed that to the thoroughness of our work. In all the cases at the time of discharge the posterior wounds were perfectly and securely healed. As has been pointed out before it is the endeavor of the otologist to obtain a dry ear. And when this is not the case, the result is not a perfect one. However, as in other conditions this is often unavoidable, or at least, strive as hard as the otologist may, the ear remains moist despite all his efforts. Some assert that failure to remove the granulation tissue in the attic at the time of operation might be put down as a cause of the persistent discharge. This might be true, but cases clear up in which these granulations in the attic are not disturbed. We would, however, urge the removal of the adenoids in these cases, just as has been recommended in middle ear disease, in which the discharge persists. In at least four cases did this procedure prove successful. Of the one hundred cases two patients were discharged with moist ears. The remainder all were dry. Out of these that were dry three had persistent perforations in the drum membrane and in the others there was a complete resolution of the membrana tympani.

The state of hearing should be an important concern to the otologist. But the average man is likely to entirely forget this particular phase. If the mastoid is healed and he does not note any discharge from the canal, he discharges his patient very often without taking a final look into the middle ear. Surely the state of hearing must concern him much less. As in simple otitides it is necessary to inflate the middle ear early in order to obtain full and permanent restoration of function, so it is necessary in mastoid cases that the middle ear should receive proper attention. As a rule if a mastoid is operated upon early, we expect practically normal hearing to return. Only occasionally does one find some slight impairment. In all of our cases in whom the middle ear became dry, with complete resolution of the membrane, the hearing returned to its normal state. So we can say that the mastoid operation does not in any way prove detrimental to the auditory function.

In conclusion we wish to state that the mastoid operation has its definite and distinct indications; that with these indications present the mastoid should be cleaned out without delay; that the operation should be thorough and complete; that in the after treatment there should be the observance and adherence to those surgical principles governing the treatment of mastoid wounds as outlined above. Only then can we hope for the avoidance of unnecessary secondary operations and look for a shortened period of convalescence with permanent union and the restoration of normal function.

691 Lafayette Avenue.

Historical Medicine

Fifty Years of Surgery—1875-1925*

JOHN B. DEAVER, M.D.
Philadelphia, Pa.

"Man's span of life," according to the psalmist, "is but as yesterday when it is passed, and as a watch in the night." Applied to the life history of surgery during the past fifty years the figure of speech becomes a reality, representing as these years do the dawn from a passing night rapidly developing into the day of brilliant sunshine. Indeed, so rapidly has the science and art of surgery advanced during these years that it is difficult to realize that most of the procedures and the armamentarium at our command today have been developed during the past half century in our history. What this same period will appear like to him who fifty years hence will be reviewing from this same rostrum a half century or a century of the achievement in surgery it is difficult to foretell. If the ideals of preventive medicine will have been as fruitful as the prophets of today predict, perhaps surgery will have outlived much of its usefulness and will have resumed its original limited field, the treatment of fractures and similar accidents. And perhaps many members of this august body, will be looking for, or mayhap will have already entered upon new fields of activity, instead of basking in the sunshine of the past and glorying in the refulgence of their present day achievement. The rôle of the prophet, however, as you all know is never a pleasant one, particularly in his own country, and I am grateful to your chairman of the Committee on Scientific Business for, and appreciate the honor of having been assigned the more pleasant and agreeable task of looking backward fifty years.

It is a selfevident fact that the phenomenal advance of surgery during this period began with the epochal discoveries of Long and Morton, and of Pasteur, and of Lister. In the 80's ether and chloroform anesthesia had already become well established, but antiseptic and aseptic surgery were still fighting their way to supremacy. The prejudices of the older surgeon were hard to overcome. He was as loath to discard the methods which had served him with a certain degree of success, as he was to give up his blood stained, germ soaked linen duster which had served him for an operating gown. It is not necessary for me to draw a picture of then and now in the operating room, nor of the complete change that has taken place in the entire field of hospital conduct and management. Rather let me proceed to pass in review as best I can some of the outstanding advances in surgical methods.

Fifty years ago, in the words of our own beloved and immortal physician poet—S. Weir Mitchell, anesthesia "the highest mercy brought by man to man," had already

> "Struck from the roll of pangs one awful sum,
> Made pain a dream, and suffering gently dumb!"

At that time and for about a decade more general anesthesia, enriched later by the addition of the gas oxygen method, was almost exclusively used, until its supremacy was threatened by the introduction of local and spinal anesthesia, this new method has widened the field of surgery and to even a larger extent has reduced the risks of general anesthesia and has transferred many types of cases from the inoperable to the operable class. Still in the process of development it offers a splendid field for research and profitable investigation. But it is doubtful whether it will ever entirely supplant general anesthesia, although combined with a light general narcosis its usefulness stands unquestioned. The first step in the introduction of local anesthesia is represented by the introduction of the local application of cocaine. The pioneer in filling what proved to be a longfelt want is Karl Koller, who in 1884, published the first account of the use of cocaine as a local anesthetic in operations on the eye. That the method filled a longfelt want is evidenced by its remarkably rapid spread and development and its adoption in practically every field of surgery. To the late lamented W. S. Halsted belongs the credit of having been the first to use cocaine in general surgery.

The early enthusiasm, however, was somewhat dampened by the toxic effects of the drug, mainly due to imperfect methods of manufacture and its consequent admixture with impurities, as well as to the limited facilities for its production, so that the demand being far in excess of the supply caused an enormous inflation in its price. But the synthetic production of the drug soon corrected both these evils, and at the same time led to the discovery of many synthetic drugs. Notable among the latter is novocaine, discovered in 1905 by Adolph Einhorn, which seems to combine the requirements of a local anesthetic without any of its disadvantages.

Thus armed with the means of making "suffering gently dumb" and enriched with the growing power of controlling infection, the surgeon boldly threw down the barriers that had hitherto blocked his path, especially in the domain of abdominal surgery. But in spite of Lister's antiseptic methods, the early days of this new era witnessed many discouraging results and thoughtful men soon realized that Lister's theory of air borne infection was only partially complete, especially when applied to intraperitoneal operations. Prominent among such keen observers stands Lawson Tait, who was among the first to emphasize asepsis rather than reliance on chemical antisepsis. Animal experimentation also helped to demonstrate the destructive action of certain chemical antiseptics on certain tissues, especially within the abdominal cavity. And at this time Pasteur himself boldly attacked the theories of some of the eminent physicians of his day on the cause of puerperal infection by showing that the infection was carried from a sick woman to a healthy one by the doctor himself, and

*Read before the College of Physicians of Philadelphia, April 1, 1925.

illustrated his theory by drawing on the blackboard the picture of the culprit—the now familiar streptococcus in chains. This may be said to be the actual beginning of the revolution in operative technic consisting of strict surgical asepsis of all instruments, the use of rubber gloves, sterilized operating gowns and scrupulous asepsis applied to everything and everyone connected with the operation. Today these measures are so much a matter of course that it seems almost banal to mention them.

Hospital construction naturally kept pace with these advanced ideas and there is the same difference between the modern hospital and the hospital of half a century ago as there is in the surgery of then and now.

I have already mentioned that the earliest field invaded by the newer surgery was the abdomen. Abdominal surgery, which before 1875 was considered more or less criminal surgery, rapidly came into its own and exploratory laparotomy was from now on considered a perfectly legitimate procedure. Indeed, the abdomen henceforth (to use the apt expression of our great and greatly beloved Keen) was destined to become the playground of the surgeon. While many of the "ectomies" now in general use had already been attempted in the early days immediately following the introduction of ether anesthesia, they were abandoned as unsuccessful and dangerous. These were now being revived under the beneficent sway of asepsis, improved technic and increased familiarity with the procedures. Not only that, but entirely new operations were being devised, many of which represent some of the most striking contributions of our era to the history of surgery.

The decade from 1875 to 1885 witnessed such important innovations as Porro's Cæsarean section with excision of the adnexæ; Freud's excision of the uterus; Lawson Tait's operation for extrauterine pregnancy. Billroth, in 1880 performed the first pylorectomy for cancer of the stomach. This was followed by a rapid succession of anastomotic operations, the first and most familiar of which is Wolffler's gastroenterostomy in 1884. The gallbladder was successfully removed by Langerbuch in 1882. Each of these procedures, modified and improved, has become a daily occurrence in all large clinics.

The year 1886 is marked by Fitz's memorable study of the pathogenesis of appendicitis, which perhaps more than any other single investigation has changed the concept of the causes of intraabdominal infection and eliminated the then prevalent term of idiopathic peritonitis from the medical vocabulary. During the next few years surgery was enriched by O'Dwyer's improved method of laryngeal intubation, a distinctly lifesaving measure, but the indication for it is being reduced to a minimum by the present day methods of antitoxin treatment for diphtheria. Mutilating bone surgery and amputations were being replaced by nonmutilating, orthopedic and plastic operations. MacEwen's osteotomy, opening large joints, restoring ankylosed limbs, belong to the period before the close of the 19th century. All these were matters of daily occurrence and enjoy a large degree of certainty of good results. Horsley's laminectomy also belongs to these years, and at this time suture of the heart was attempted with success. Gynecology was enriched by Wertheim's operation, and so the story could proceed from one innovation to another and from one advance to another.

During this period of evolution it was but natural that the instrumental armamentarium of the surgeon should keep pace with advance in surgery. The number of new devices is legion, but it may be well to mention some of the more outstanding ones which have facilitated our work. Hemostats were modified and improved, the Kocher forceps is a notable contribution; the ingenious Murphy button still serves a useful purpose for anastomotic operations; although most surgeons today have returned to suturing as a more desirable method of joining resected viscera. A notable innovation is also represented by the Paquelin cautery. Posture during operation came in for adequate consideration and we use the Sims position, the Trendelenburg position, and the like, on tables expressly fashioned for such changes in position. Practically every surgeon has devised some modification of the usual instruments to facilitate his work.

It was but natural that the entire change in surgical methods, and I may say surgical thinking, should demand increased facilities for diagnosis. The development of endoscopy at this time supplied this desideratum and placed at our disposal the ophthalmoscope, the esophagoscope, the bronchoscope, the rectoscope, the cystoscope, and other instruments by which direct inspection of pathological processes has been greatly facilitated. Whether these devices gave the impetus for the rise of the surgical specialties, or whether the rise of the specialists produced the instruments, the fact remains that the years between 1890 and 1900 saw the separation of surgery into specialties which today is taken entirely for granted, such as the treatment of diseases of the eye, ear, nose and throat, genitourinary surgery, and so on.

The surgeon of fifty years ago might have been able to predict some of the advances in surgery which I have attempted to record, but it is doubtful whether anyone, no matter how imaginative he may have been or how optimistic, ever dreamed of the possibility of direct inspection of practically all parts of the body as provided for us by that most notable and I may say romantic invention of the physicist, Wilhelm Conrad Roentgen. Does it not sound like a page from a romance that the accidental placing of a glowing electric light bulb upon a book containing a metal key and under which lay a photographic plate, should have led to the discovery of a ray of light, invisible to the eye, capable of traversing solid substances! From now on the demonstration of pathological changes, of injuries to the bony system became possible. Not only that, but with development of the roentgen ray today we are able to inspect the body viscera and observe function so that the roentgen ray diagnosis has become an almost indispensable diagnostic adjunct, particularly in disease of the lungs, the heart, gastrointestinal and genitourinary tracts. However, I have on more than one occasion registered my protest against allowing x ray diagnosis to replace rather than to confirm or enhance clinical diagnosis. The danger is an ever present one and the warning bears repetition.

During these years then, the years of acquisition, if I may so call them, we were learning much about how to operate, and at the same time why to operate and when to operate. In other words, surgical pathology rapidly found a most important place in surgical endeavor. Hitherto pathology had been limited practically to external pathology, and the dead in the postmortem chamber were teaching the living. But henceforth it was destined to be superseded by internal pathology, whereby the living teach the living. Pathology of the living is the term for this so happily coined by that master surgeon, Sir Berkeley Moynihan. This unquestionably represents the most vital factor in medicosurgical advance. Animal experimentation, of course, has played an important rôle in progressive work, indeed it represents a large part of the pathology of the living, and through it there have been opened up entirely new paths of investigations for the physiologist, the surgeon, and the pathologist, such as glandular function, neuropathology and localization, functional pathology of the gastrointestinal tract, and so on.

The phenomenal development of bacteriology during these years provided another notable contribution to our knowledge of both why and when to operate. New discoveries in this sister science succeeded each other with bewildering rapidity, and were gradually routing from their lairs the hidden causes of many infections. To mention only a few I may call attention to the discovery of the bacilli of anthrax, of gas gangrene, of diphtheria, or of meningitis, the gonococcus, the pneumococcus, the streptococcus, the staphylococcus, and the colon bacillus. These naturally led to the discovery of others related to visceral lesions which concern the medical man and the surgeon alike in their various fields of activity.

Closely allied to this new avenue of research is the science of serology which has written an entirely new chapter in the history of our profession. It has revealed the importance of the organs of internal secretion and has thrown light on many obscure and delicate biological reactions. Its demonstrations of the influence of glandular activity on metabolism and vital functions, on growth and regeneration, are among the most noteworthy contributions to the medical sciences. Surgically its import lies in the revelation of the interdependence of all the components of the endocrine system which has brought about so marked a change in our conception of certain disease processes and a resulting change in therapeusis.

In line with this is the recrudescence of blood transfusion. The idea of blood transfusion was germinated in the minds of surgeons for many centuries of time. Indeed, it was attempted as early as 1667 by a Frenchman, Denis, but with such results that any further use of the procedure is said to have been prohibited by parliamentary edict. It was repeated from time to time by other surgeons with indifferent or altogether unfavorable results. No wonder, as for its success was needed not only the strict antisepsis of modern times but also the advance in vascular surgery of our era. Provided with these and with a thoroughly physiological habit of thought, it remained for our own Crile, about thirty years ago, to reintroduce the procedure which in its subsequent development has become one of the most useful measures at the disposal of the surgeon in great emergencies. The correlated method of storing up collected blood with the addition of sodium citrate has added much to the value of the procedure.

The why to operate is but the application to practice of a new manner of thinking which was developed during these years. It can be best expressed as the pathologicophysiological habit of thought. This new habit of thinking is no doubt responsible for the return of surgery to the dignified profession which it is today. Where formerly the surgeon was merely the handyman for the internist, today the internist is, or should be, glad to have the surgeon not merely as his operator but as his cooperator. Surgery and medicine are now too closely allied ever again to be so widely separated as in former days. It is to the interest of the patient, the final goal in all our work, that this entente becomes closer and closer in order to insure the best results. I shall revert to this later on. The surgeon's knowledge of when to operate should be called into action early and it should be left to him and not to the internist to decide. Every surgical disease has "its surgical hour" which taken at its best bids fair to lead to victory.

If, as I have intimated, the new science of bacteriology received a marked impetus through the new habit of surgical thinking, surgery in turn owes it a vast debt in one of its most triumphant fields of usefulness, and that is the recognition of the surgical hour that bids fair to lead to victory. We need no figure to convince us that the timely recognition of, and timely intervention in, acute disease of the abdomen is one of the outstanding achievements of modern surgery. There is no way of reckoning the countless numbers that have been saved by this advance. And for many chronic infections there is the possibility of a cure by removal of the infected organ, such as the appendix, the gallbladder, chronic pus tubes, cystic ovaries, infected uterus, the diseased kidney, the enlarged prostate, the spleen.

It may be consoling to the laymen particularly that there still are some organs that have escaped the scientific greed of the surgeon, to use the term of a French surgeon, such as the pineal gland and the suprarenal capsule, the pancreas as a whole, the medulla oblongata, and the cardiac valves.

But even the heart and the lungs are nowadays not closed to the path of the surgeon's knife. In some quarters claims have been made that surgery has cured certain types of cavernous pulmonary tuberculosis and bronchiectasis. Operative intervention in pulmonary abscesses has become much safer than ever before. Surgery of the heart, it is true, is being written about probably more than it is being practised, but the results are encouraging, considering that this is the early stage of development of a very delicate procedure.

Brain and spinal cord surgery have made remarkable strides during the past twenty-five years, particularly in the localization diagnosis of disease of these regions, and this advance is one of the best illustrations of the cooperative work of the clinician and the surgeon. Although the special structure and

physiology of the brain and its centres interferes with the absolute success of surgery in this region, nevertheless there can be recorded a distinct gain in the treatment of tumors of the cortex and even of deepseated ones in the cerebellopontine angle and the hypophysis, which together with the surgery of the spinal cord excites the well deserved admiration of the profession. Rapid strides in vascular surgery mark an outstanding achievement of our time, especially in the treatment of traumatic aneurysms.

In a retrospect of more recent years war surgery supplies an important chapter. It is interesting to note that the emergencies aroused at the time witnessed a return to the early methods of chemical antisepsis as represented by the much lauded Dakin's solution. Débridement of wounds, although practised many years ago and much in vogue even before the war, was revived. Plastic surgery received a tremendous impetus during these years, the effects of which are perhaps more noticeable in civil surgery than any other procedure stimulated by the exigencies of war.

It remained for the younger generation to evaluate what the war brought forth in surgical methods, and I shall leave this aspect of my subject to them.

Our history, as I have endeavored to point out, shows an ever increasing tendency toward a consideration of why and when to operate, a practice that was scarcely possible before this era. Formerly the main reason for operation was the immediate saving of life, without a great deal of thought of the resulting possible morbidity. Today we are in a position to aim at conserving life with a very high degree of restoration of function. The essential desiderata for attaining this ideal and for which the coöperation of all branches of the medical sciences must be brought into play are adequate diagnosis, and to no less extent adequate preoperative and postoperative treatment. These are part of the physiological habit of thought which marks our time, but they demand the free and willing coöperation of the clinician, the surgeon and the scientist.

We can point with pride to the problems that have been solved, but we dare not fail to realize that there are still many which seem to baffle solution. I need but mention our ignorance of the cause of cancer which makes our treatment of that malignant disease still a matter of empiricism, and which of itself is enough to humble the proudest among us. Perhaps the solution of the problem will also come from one of our sister sciences. Medicine and surgery owe a vast debt to nonmedical men; Pasteur was a chemist, and Röentgen a physicist.

Experiments on Man Demonstrating the Dynamogenic Power of a Liquid Extract of Animal Testicles

M. BROWN SÉQUARD

Translated from *Archives de Physiologie*, Fifth Series, No. 1, 1889, p. 651, by L. L. Stanley, of San Quentin, California.

(*Concluded from page 229*)

Because of a natural impetuosity, and also to avoid a loss of time, I had up until the age of sixty, the habit of going up and down the stairs almost on the run. This mode gradually changed and I came to the point where ascending and descending were quite slow. It even became necessary for me to hold to the handrail on the steep stairs. After the second injection, I affirm that I had regained my lost propensities and had without realizing it regained my old habits. The strength of my limbs measured in comparison to the week preceding my experiments and during the month which followed the first injection has been remarkably increased. The flexors of my right arm registered on the average of thirty-four and one half kilograms (from thirty-two to thirty-seven kilograms). After that injection the average was increased to forty-one kilograms (from thirty-nine to forty-four kilograms), the gain being consistently from six to seven kilograms.

The flexors of the forearm have likewise recovered the strength which they had twenty-six years ago. They recorded at that time (1863) an average of forty-three kilograms.[4]

I will say that if some think that nothing is more variable than the strength as measured by the dynamometer, they come to that opinion because they do not take into consideration the state of health of the subject nor the time of day the test is made. If digestion is good and if the other functions are not impaired, one finds that the strength as measured by the dynamometer at the same time of day, does not vary more than five to nine kilograms. But it is necessary that the subject always hold the instrument in the same manner and that he grip in all tests with all the strength that he can. I have always kept track of all the circumstances and consequently I can say that the strength which I gained has been considerable.

I have measured by comparison the flow of urine before and after the first injection. The circumstances in both cases were the same. The compared output was that which followed the same kind of a meal in which I drank the same amount and the food I ate was of the same kind and quantity. The shortest length of the stream during the ten days preceding the first injection was at least one fourth shorter than it was during the twenty days which followed. It is certain that the power of the spinal cord on the bladder was considerably increased.

Perhaps the most distressing of the misfortunes

[4]Since 1860 I have recorded in the same manner almost continuously the strength of my forearm. From that time up to 1862 I recorded at times as much as fifty kilograms. During the last three years from 1886 to 1889 the greatest which I could record was thirty-eight kilograms. This year before the first injection the greatest was thirty-seven kilograms. Since that injection it has been forty-four kilograms.

of old age consists in the weakening of the power of defecation. The expulsion of fecal material had become with me in the past ten years extremely laborious and it was almost impossible without the use of purgatives or artificial means. I made regular use of laxatives, not so much for the constipation which was very great except at rare intervals, as to increase the motive action of the intestinal well.

During the fifteen days which followed the first injection a radical change took place in the reflex of defecation; I had less need for laxatives and moreover, the expulsion of fecal material equally as large and hard was accomplished without mechanical assistance or lavage. There had taken place a return to a normal condition of a number of years before.

I will add that intellectual effort became easier than it had been for a long time and I have regained in that respect all that I had lost. I can say also that my other forces, not lost but decreased, have been remarkably strengthened.

It is evident from these facts and others of which I have not spoken that all functions dependent upon the dynamic power (*la puissance d'action*) of the nerve centres and especially the spinal cord are remarkably and rapidly improved by the injections thus employed. The last injection was made on June 4th, over three and one half months ago. For more than four weeks there has been no change in me, all the improvements having persisted. But gradually and rapidly since July 3d, have noticed an almost complete reversion to the condition of weakness which existed before the first injection. This gradual loss of strength is an excellent proof in that it shows the favorable influence upon me of the subcutaneous injections of a fluid taken from the testicles.

V.

I am writing about that which followed since last June, "I hoped that other physiologists of an advanced age would repeat these experiments and show whether the results I obtained upon myself depended upon my own personal idiosyncrasy or not. As to the question of knowing that it is a sort of autosuggestion without hypnotism to which can be attributed entirely the changes which have taken place in my organism, I do not wish to inquire into at this time.

"That interesting piece of work by Dr. Hack Tuke (*Illustrations of the Influence of Mind Upon Body,* 2nd edition, London, 1884, 2 volumes) is full of the facts showing that many changes which I have observed upon myself after the injections which I have taken, could be caused by the influence of a single thought (*la seule influence d'une idée*) upon the human organism."

In the history which I will give in another place of a considerable number of cases in which injections similar to mine have been made, without the individuals knowing whether it was desired to find out whether they gained in strength, that result has in fact been obtained.

It is therefore evident that it is not a result of a kind of autosuggestion and that the forces of the nerve centres are increased and that it can well be to a special action of the fluid injected that this effect is due.

Papworth, the First Village Settlement for the Tuberculous.—"Enquiries about Papworth continue to be incessant," writes P. C. Varrier-Jones, medical director of this tuberculosis colony at Papworth Hall, Cambridge (*World's Health,* August, 1924). "What is Papworth? . . . Why has sanatorium treatment failed? Papworth has not only revived the present system of sanatorium treatment, but has extended it. . . . Papworth has tried to answer the question: Why does a working man consumptive break down after a period of sanatorium treatment?—and provide a solution. The usual answers given are: 1, that his home conditions are unsatisfactory. . . . 2, that his conditions of work are against him . . . 3, that the economic conditions of the workaday world are against him." Papworth strives to fill all these lacks.

The Cambridgeshire colony now numbers 196 persons, including 70 children, according to its report for 1924. Patients are admitted in all stages of consumption, and the work they do is assigned according to their strength. There is no limit to their term of residence, and they are encouraged to settle permanently with their families in the colony. It thus becomes possible for persons whose working capacity is below normal to continue doing part time work often for many years, instead of being pushed to the wall in the competition of the outside world. This not only makes the patient who is capable of part time work a happy and useful citizen, but the whole plan is a sound business proposition, for it keeps the man from going under a short time after being dismissed from the ordinary treatment because he tries to compete with workers who are more able bodied than himself.

Schopenhauer and Beards.—Schopenhauer wished to have the wearing of beards banned, not only because the custom was "immoral" but because they had a lustful character pleasing to women. Many times he expressed this opinion in the course of his polemics with Hegel who wore a tawny beard. "The length of the beard," he said, "is in proportion to the state of barbarity of the times. This is why the barber flourished in the Middle Ages, that period of rudeness and ignorance which our noble contemporaries are actually striving to imitate in dress and architecture. They say that the beard," he adds, "is natural to man. It is true that it suits man perfectly in a state of nature, just as civilized man ought to be clean shaven to show that brute force, of which the beard is the evident symbol, must give way to law, order and manners. The beard emphasizes the animal portion of the face and makes it prominent; it thus gives a particularly brutal appearance to its wearer. Watch a bearded man while he is eating. . . . The police ought to forbid beards because they constitute a half mask under which it is difficult to recognize a man. The changes of expression which indicate the life of the spirit are to be found chiefly about the mouth; it is a thing which can under certain conditions become dangerous, and for deceiving the watchful eyes of adversaries, nature, who knows the *homo homini lupus,* has given man a beard. For this reason woman, in whom self knowledge and dissimulation are innate, cannot pass by it."—Translated from *Æsculape.*

Aniline Dyes in the Study and Treatment of Gastrointestinal Disorders*

G. REESE SATTERLEE, M.D.,
New York

The therapeutic use of aniline dyes has until recently been quite restricted. The low toxicity of the dyes, when compared with other more widely used antiseptics, will in all probability result in their more universal usage. Methylene blue (1) was the first of the dyes to receive special study. It was used in Europe between 1886 and 1898 for the treatment of malaria and neuralgia. Since that time numerous satisfactory reports concerning its use in eye, ear, nasopharyngeal and genitourinary specialties have been published.

At the present time I am concerned with the study of the therapeutic effect of two aniline dye substances —acriviolet and acriflavine. I have been materially aided by the experienced advice of Dr. John W. Churchman, who has demonstrated the penetrating, antiseptic and nontoxic properties of both these dyes in solution when used in the human organism. For three years past clinical experiments have been conducted at the New Jersey State Hospital, at Trenton, under the direction of Dr. Henry A. Cotton, with the cooperation of Dr. John W. Draper and Dr. John W. Churchman. This work has been confined chiefly to a study of the action of acriviolet as an antiseptic for the colon and has been used largely as a preliminary measure to colon resection.

Acriflavine and particularly neutral acriflavine is less irritating to the tissues than acriviolet, but it has been found that its value as a germicide is not so inclusive as acriviolet, which destroys both gram positive and gram negative aerobic bacteria. For local use in the specialties, except possibly in gastroenterology, acriviolet has replaced acriflavine because of this broader power. The object therefore of my own presentation of the subject at this time is to furnish a preliminary review of the methods and results of administration of acriviolet in gastroenterological disorders. While the use of acriviolet in this manner is undoubtedly subservient to other more generally accepted therapeutic measures, there is no doubt that its physical properties, as above mentioned, render it an invaluable aid to treatment. In order properly to demonstrate the clinical value of the drug, every effort should be made to exclude such simple pathological conditions as tend to return to normal even in the absence of treatment, and we should be wary in accrediting undue merit to the drug when used in these conditions by believing that it has shortened the period of recovery. It is obvious that there can be no adequate control in handling such conditions. The enthusiasms of youth must be checked!

One of the great difficulties encountered in the administration of acriviolet solution to the colon mucosa arises from the fact that the colon tolerates the drug imperfectly. In the average case the highest concentration of the drug which can be used in colon therapy is from 1:25,000 to 1:35,000. The routine administration is as follows:

1. A cleansing enema of soapsuds is given. This is made alkaline if the reaction of the feces is acid.

2. One to two quarts of a 1:35,000 hot aqueous solution of the dye is prepared and introduced into the colon.

3. The solution should be retained as long as twenty minutes, if possible, and then expelled.

This treatment may be given daily or less frequently when indicated. The strength of the solution should gradually be increased up to the limit of tolerance. In a few individuals who have become accustomed to the drug, a strength of 1:10,000 has been tolerated. In this connection the interesting observations of Dr. Churchman upon the effect of the dye in much stronger concentration is worthy of close attention. In the surgical clinic of the New Jersey State Hospital he found after injecting the lumen of an isolated segment of colon exposed during laparotomy with a solution of dye running as high as one per cent. in concentration, that cultures made from this segment, after twenty minutes' contact with the dye, were sterile with regard to aerobic organisms. He qualifies this statement by saying that while the sterility is undoubtedly due in great part to active bacterial inhibition and destruction during the twenty

*Read before the American Gastroenterological Association, Atlantic City, May 26, 1925. This study was aided by a grant from the Andrew Todd McClintock Foundation for the Study of Gastrointestinal Disease.

minutes' exposure, it is possible that it may have been aided by dye carried over into the culture. No permanent damage to the colon could be demonstrated as a result of this procedure. The possibility of the use of the dyes in much stronger concentration in ordinary medical treatment is therefore to be considered.

If it is desired to destroy all the gram negative flora in the colon, irrigations with neutral acriflavine solution 1:6,000 may be employed. Administration of the neutral acriflavine by mouth is accomplished by the use of enteric coated pills. This dye is recovered in the feces and its action diminishes intestinal fermentation. On the other hand, the administration of acriviolet by mouth has not yet been perfected. The drug is irritating to the stomach and its action is very possibly altered by the acid gastric juice. To avoid this complication the administration of acriviolet by means of duodenal catheterization may be highly successful, and its use in this way in some of the case histories hereto appended is demonstrated.

Churchman found gentian violet bacteriostatic for gram positive organisms. He found further that mixing the dyes did not affect the selective bacteriostatic action of either dye. Crossley (2) states that the action of the dye may be chemical. The staining properties of the dyes do not completely correspond to their toxicity. Gentian violet and acid fuchsin stain gram positive bacteria, but acid fuchsin is not toxic to these bacteria. The action of gentian violet is said to be due to a colorless radical of the sulphonol group. Hagen (3) suggests that the selective action may be due to reactions between the ions of the dye and of the bacteria. Churchman has published numerous articles in connection with his experimental work, reference to only one of which will be given here (4). Some of the important facts are the power of the aniline dyes to penetrate into the cells and tissues of the body and into living bacteria; their nontoxicity, as proven by injecting enormous quantities into rabbits without poisoning; their harmlessness when injected into the knee joint. The blood serum of rabbits which have been injected with the dyes shows a bactericidal action which disappears in two hours.

It is perhaps necessary here to mention a few limitations of the aniline dyes. They are not very powerful bactericides and may be impaired by environment and inhibited by serum. The secretions may form a barrier to penetration. Their solution is unstable and should be made fresh every twenty-four hours. The efficiency of gentian violet solution is increased by heat. Acid fuchsin is equally efficient hot or cold. Acriviolet is put up in tablet form, each tablet containing 0.156 gm., which when dissolved in fifteen c. c. hot water makes a one per cent. solution. The powder dissolves readily.

CASE HISTORIES

Case I.—Physician, complaint chronic intestinal toxemia of long standing. He reported good results on himself by altering the intestinal flora and as toxic results a "peculiar and very decided putrefactive odor to the stools." He had been taking four grains of acriflavine or of gentian violet daily by mouth and 1:10,000 solution by enema daily. He reported also muscular and neuritic pains, all of these symptoms disappearing in a few days on discontinuance of the dye. Acriflavine by mouth gave a pale orange coloring to the urine and gentian violet a pale violet shade. It was possible that the patient was using more of the dye than was necessary over a long period of time and that the symptoms were from epithelial irritation.

Case II.—Student, male, aged twenty-three years, married. Complaint, nausea, vertigo and constipation. A previous appendectomy had been performed with temporary relief and improvement. Physical examination showed some abdominal distention, a large liver, tight rectal sphincter, hemorrhoids and fissure. Hemorrhoidectomy was performed immediately. Later radiographs of the colon showed general colitis with poor haustration, dilatation of the transverse colon and severe spasm of the ascending colon and marked colon irritability. Although this case gave no marked colon symptoms the main lesion was in the colon, which was probably an ascending infection from proctitis.

Treatment consisted in antitoxemia diet, autogenous colon vaccines, colon irrigations with acriviolet solution and neutral acriflavine by mouth. The result was very satisfactory.

Case III.—Female, aged forty years, married. Complaint, large amount of flatulence, poor appetite and sleep. In December, 1922, a pelvic operation with removal of the appendix, both tubes and ovarian resection for inflammatory condition, was performed. Following the operation the patient had considerable difficulty with her bowels, a spastic condition of the colon with marked fixation in the pelvis. Chronic colitis and stasis. Treatment had been an antitoxemia diet and autogenous vaccines and acidophilus milk. For six months of this treatment the condition remained stationary. Recently the patient had been given neutral acriflavine in coated tablets, one half grain twice a day. The results on flatulence and general intestinal condition were better than by any previous treatment. The dye was given up to a physiological limit, as shown by yellow discoloration in the urine. The most marked result was the improvement in flatulence, which was effected, at least in some extent, by the acriflavine.

Case IV.—Male, twenty years of age, single. His complaint, constipation with marked toxemia, neuralgic and myalgic pains, general acne and incapacity. The colon showed marked stasis and pericolic adhesions. The treatment consisted in the antitoxemia diet, which was effective for the constipation and the administration of acriviolet solution through the duodenal tube. There was improvement in the acne and toxemia after two weeks' treatment.

Case V.—Female, aged sixty-two years, married. Complaint, chronic intestinal invalid with colitis and colon spasm, multiple focal infection of seven years' duration. The patient had been thoroughly detoxicated but still had colon spasm and neurasthenia. In addition to immunization by autogenous vaccines, a restricted diet had been necessary and the colon spasm was relieved by means of enemata of acriviolet solution. Acriflavine by mouth was very irritating and given up. The patient was especially hypersensitive to milk protein, egg protein, adrenalin and aniline dyes.

Case VI.—Male, forty-three years of age, married. Complaint, loss of energy, long standing constipation, loss of mental poise and marked neurasthenia. There was marked oral infection and extreme toxemia and depression. The radiographs showed colon stasis and right sided pericolitis. Treatment consisted in the removal of the dental infection, but not of tonsillar infection on account of the patient's prejudice to tonsillectomy. Autogenous vaccines of the colon type were of great value in the early treatment, also neutral acriflavine by mouth and acriviolet irrigations by rectum. The patient was very sensitive to both, acriflavine being substituted in strength of 1:6,000 for irrigations. However, the treatment was continued with excellent results.

Case VII.—Male, thirty years of age. Complaint, lowered efficiency and vitality; secondary tendency to constipation and gas. The patient had had stomach upsets for fifteen years with rapid pulse, flatulence and slight constipation, nervousness, pains, phobia and insomnia. X ray examination of the colon, 1924, showed a large redundant colon with low grade inflammatory changes particularly on the right side. Here there was an inseparable coil at the hepatic flexure. The stools were putrid with a great amount of trichomonas intestinalis. The patient had hemorrhoids and tight sphincter. The first treatment was hemorrhoidectomy. He was then placed on an antiputrefactive diet and large doses of thymol in the supposition that the trichomonas in such large quantities in the stool might be pathological. He was given autogenous colon vaccines. The colon was irrigated with acriviolet solution 1:35,000. Gradual improvement with the disappearance at times of the trichomonas followed the irrigations with the dye. Severe reactions followed the vaccines.

After six months of this treatment there was marked physical, mental and nervous improvement with corresponding improvement in the appearance of the colon as shown in the lantern slide. In addition to giving acriviolet by rectum, fifty c. c. of a 1:1,000 solution of the dye (0.052 gm.) were given by duodenal intubation. Seventy-two hours later, the dye was recovered in the feces and there was no trace of trichomonas. This method of administration of acriviolet solution has been tolerated by the patient. As a result the stools have been much larger, well formed and contained about twenty-five per cent. less bacterial flora. Physical well being has followed in exact proportion to the improvement in pathological findings.

It is not intended as yet to draw conclusions as to the therapeutic value in the intestinal tract of these dye substances as the therapeutic experience is limited. The results so far are favorable and show a very low grade of toxicity if any. Further studies will be published.

I wish to acknowledge my indebtedness to Dr. Churchman, not only for his extensive experimental studies upon the action of the dyes on bacterial life both inside and outside of the body, but also for his aid in the preparation of this article. I also acknowledge the invaluable aid of Mr. Michael Turpak, of the Andrew Todd McClintock Memorial Laboratory, in conducting the routine laboratory research work.

Gastrointestinal Manifestations of Food Allergy*

ALBERT F. R. ANDRESEN, M.D., F.A.C.P.
Brooklyn, N. Y.

In the past few years medical literature has been filled with articles on asthma and hay fever and their relation to protein sensitization. Only occasionally, however, has there been any reference to the equally definite and often more distressing manifestations of allergy in the gastrointestinal tract. Sensitization or allergy is closely related to the problem of immunity and anaphylaxis, both in principle and in manifestations. As long as the tissues of the human body are able to produce an antibody (probably really a tissue enzyme), to destroy or change a certain protein, living or inert, so that it does not act as a poison to the tissues, that individual is "immune" to that protein. When certain tissues become sensitized to the protein, these tissues will be affected, either showing a noninflammatory reaction (hyperemia) in the case of the inert protein, or an inflammatory reaction (infection) in the case of the living bacterial protein. Again, a sudden severe allergic reaction corresponds to an anaphylactic reaction, and protein desensitization is accomplished in the same manner, and produces the same results, as active immunization.

In the case of infection, it is not plain as yet whether antibodies are made in some one organ or tissue of the body, or whether each separate tissue must produce its own antibodies, but that the latter is the case seems probable from the fact that certain strains of bacteria seem to have a predilection for certain tissues, or in other words that certain tissues are susceptible to certain bacteria. In the case of allergy this "selectivity" has long been recognized, it having been demonstrated that different tissues may be sensitive in varying degrees to the same or to different proteins. Thus, in the same individual a sensitization of the nasal mucosa to pollens may produce hay fever, of the bronchial mucosa to some emanation, asthma, of the skin to a vine or shrub, erythema or vesiculation, or of the gastrointestinal

*Read at meeting of American Gastroenterological Association, May 26, 1925.

mucosa to a food protein, spasm or angioneurotic edema of this tissue.

The mechanism or chemistry of allergy is no more understood than that of immunity. The same theories and nomenclature applied to one can be applied to the other. Further confusion has been caused by the demonstration that identical reactions can be produced from inorganic substances, such as metals and drugs, and even from physical agents, such as light, heat, cold and mechanical irritation. A complete revision of our theories of immunity is in order.

The question whether it is a whole unchanged protein which causes the allergic reaction, as has for so long been held to be the case, is still an open one. It was held at one time that true food allergy could only occur where a gastric achylia was present, thus permitting unchanged protein to be absorbed. Yet in my group of cases, only twenty per cent. showed an achylia, and the symptoms of these did not differ from those in cases showing a normal or very high acidity. It has been suggested that the reaction may be due to some split protein or protein derivative, perhaps related to histamine, and that the whole problem is very closely bound up with the endocrine system, especially with parathyroid function and with calcium metabolism. The effects noted in asthma, in tropical sprue, and other allergic conditions, from calcium and parathyroid or adrenal therapy, help to sustain this contention.

It has been recognized, almost from time immemorial, that certain foods would cause certain untoward gastrointestinal reactions in certain individuals. The "gas" produced by certain legumes, the diarrhea following the eating of lobster, the vague uneasiness after drinking much buttermilk or cider, have been personal experiences to which many of us have been subjected. Individuals have often realized the specificity of the reaction in regard to certain foods. Careful observation of many of the more marked cases has led to a revision of previously conceived notions in regard to the frequency of this disease. In the first place it has been found that allergy is a hereditary condition, being transmitted in close conformity to the Mendelian law of heredity. While allergy in general, however, is thus transmitted, the same tissues need not necessarily be sensitized in different members of the family, nor need the proteins be the same. It is generally true that an individual is usually sensitive to more than one protein and that more than one group of organs is sensitive to the same or to different proteins. Thus, in a family that I have studied the father has had fever, asthma and chronic eczema; the mother, diarrhea and migraine; the daughter eczema and diarrhea, and the son, hay fever.

GASTROINTESTINAL MANIFESTATIONS OF ALLERGY

The gastrointestinal manifestations of allergy are various, and are said to be caused in two ways: first, by direct irritation of the gastrointestinal tract from the presence of the offending protein within its lumen, and secondly, as a part of a general allergic reaction due to absorbed protein. In most cases both factors probably play a part. Direct irritation would be the cause of the vomiting or diarrhea, or both, following sooner or later after ingestion of the protein, and of other irritative symptoms, ranging from an unpleasant uneasiness or "gassy" sensation all the way to the severe spasms, resembling biliary or renal colic or intestinal obstruction. As a part of a general allergic reaction, and associated with similar manifestations in the skin or bronchopulmonary tract, would be classed such conditions as purpura, urticaria and angioneurotic edema, which have been repeatedly shown to occur in the mucosa of the gastrointestinal tract. It is highly probable that many of the symptoms formerly attributed to intestinal toxemia, and rapidly relieved by a meat free diet, have really been due to sensitization to some meat protein, especially as the observation was frequently made that such symptoms as headache, nerve pains, coughs, and skin eruptions would often occur too soon after eating meat to be accounted for by the elaborate process of decomposition and final tissue absorption.

DIAGNOSIS

The diagnosis of food allergy is often difficult. Gastrointestinal manifestations may resemble so closely those of practically any of the organic lesions of the gastrointestinal tract, that the first requisite is a complete gastrointestinal study, including all laboratory and röntgenological examinations, to rule out such organic lesions. It must be recognized, however, that allergy may exist coincident with organic conditions, in fact, that the irritation and lowering of the resistance of the tissues caused by allergic reactions, may be a factor in producing gastrointestinal infections or neoplasms. Also, sensitization to bacterial proteins, that is, susceptibility to certain forms of bacterial infection, is a frequent accompaniment of allergy.

Due to the fact that allergy is hereditary, a history of allergic manifestations in the patient's parents or family is suggestive. As mentioned before, while the patient may exhibit gastrointestinal symptoms only, the parents or brothers and sisters may show other manifestations, such as asthma, hay fever, urticaria, chronic eczema or migraine. In the individual, a history of previous or coincident manifestations in other tissues than those of the gastrointestinal tract is very helpful. Hives in earlier life, bilious headaches, frequent coryza, especially in summer, asthma, angioneurotic edema, eczema, epilepsy, or other known or suspected allergic phenomena, should create a suspicion that the patient's gastrointestinal symptoms may also be due to protein sensitization.

SYMPTOMS

The symptoms of protein sensitization of the digestive tract are due to reactions in this tract comparable to those in other tissues, and are in the main of two types, mucosal and neuromuscular. The mucosal reactions, ranging from mere hyperemia to angioneurotic edema, may cause symptoms varying from a vague uneasiness or feeling of fullness, often attributed to gas and accompanied by aerophagia, to actual obstructive symptoms where the swelling has occluded the intestinal lumen. Cases of the latter type are occasionally subjected to operation, the surgeon either discovering no signs of obstruction or observing a general edema of the bowel, disappearing rapidly during manipulation. The mucosa of the mouth and pharynx shows reactions in the form of canker sores or of angioneurotic edema, the latter a

serious condition, especially if associated with edema of the larynx. The anal and rectal mucosa may exhibit the typical reactions, the condition often resembling a severe proctitis, and in fact, due to the infective material in the lower bowel, often resulting in actual ulcerative proctitis, sigmoiditis and colitis. Pruritis ani is often due to allergy. Bowel hemorrhages, often quite extensive, and resulting from surface oozing or from mucosal denudation or ulceration, are occasionally seen.

Of the neuromuscular reactions, the symptoms due to spasm are often confusing, and it is in cases of this type that many futile operations are performed as a result of insufficient study. Spasms of the pharynx, larynx, or esophagus, often attributed to and unrelieved by operation for various nose and throat conditions, are frequently of allergic origin. Spasms of the stomach and bowel, especially marked at the areas of more marked irritability, such as the pylorus, ileocecal region, transverse colon, pelvic colon and rectal sphincter, may cause symptoms varying from a sensation of "peristaltic unrest" to severe colicky pains, which with tenderness, due to the mucosal reaction, may closely resemble biliary, appendicular, renal or intestinal colic. Such cases are frequently subjected to multiple operations, the colicky attacks of course persisting after each operation. Milder spasms may merely induce reverse peristaltic waves, and cause such symptoms as epigastric fullness, heartburn, sour regurgitation or vomiting. Increased peristalsis, manifesting itself in diarrheas, acute or chronic, the latter often followed by rectal complications such as hemorrhoids, is one of the common allergic reactions.

While many or all of the symptoms just mentioned may also be caused by organic conditions, a suspicion that they may be due to allergy should be aroused if they show certain characteristics. First, we may suspect allergy if the symptoms occur at irregular intervals, not explainable on any other basis, and possibly with a history of variation from the usual dietetic habits just preceding the attacks, or coincident occurrence of other allergic manifestations, as, for instance, where urticaria, vomiting and diarrhea may follow the eating of a fish dinner. Secondly, if the symptoms occur on certain days of the week, especially in persons of methodical habits of eating, or in individuals living in institutions where the same foods are served on the same day each week, sensitization to one of these foods may be suspected. An example of this is seen in patients who have a headache and vomiting attack or diarrhea every Monday morning attributed to underexercise and overeating on Sunday, but really due to some article of food not eaten on weekdays. Third, sensitization is proved in cases in which the patient has discovered for himself that certain foods in large quantities may cause marked symptoms, and so has contented himself with small amounts of these foods each day, as, for instance, in cases where the individual knows that a glass of milk will invariably "act as a cathartic," but does not suspect that the milk used in his beverages, cereals and puddings is causing his heartburn and abdominal cramps.

Examination of a patient with allergy does not show anything characteristic except in cases where some of the skin or mucosal manifestations mentioned before are visible. In some cases the patient is well nourished, in others emaciated to a point suggesting malignancy. Various organic lesions may be found, but as said before these do not exclude the coexistence of allergy. The blood count, especially during the attacks, may show a marked eosinophilia, and eosinophile polymorphonuclear leucocytes have been seen in large numbers in the mucus obtained from the bowel of diarrheal cases. Gastric analyses may show an achylia, although this was true in only about twenty per cent. of my cases. Gastrointestinal x ray study, in the absence of any organic findings, may show the presence of various unexplainable spasms (cardiospasm, pylorospasm and colonospasm) or of disturbances of motility, usually hypermotility.

SPECIFIC TESTS

The specific tests for the determination of food allergy are of two kinds, dietetic and dermal. The dietetic test, really the only absolute test for gastrointestinal allergy, has for its object the discovery of certain foods which when taken by the patient will invariably produce the symptoms complained of, and when withheld will result in more or less complete relief, depending on the amount of organic change caused by long continued allergic irritation.

There are two ways in which effects of diet may be studied. In well nourished patients, all food may be withheld for three days, the patient being given only water or a rice and water diet—the old Bulkeley diet. If due to food allergy (and not to rice), the symptoms should disappear or be markedly alleviated, and a careful written record of the results of adding one or more articles of food to the diet on successive days will disclose the food or foods to which the patient is sensitized. The other method consists in having the patient keep on a fairly full diet, but to vary the foods taken to as great a degree as possible, especially those taken just preceding an attack of the symptoms suspected of being of allergic origin. A detailed daily record of the diet and symptoms, showing the time and character of the food eaten and the time of onset and duration of symptoms, will in from two to four weeks almost invariably establish the identity of the offending foods. In the cases where the allergic reaction is continuous or occurs every day, the symptoms being due to some common daily article of diet like milk, egg, or wheat, dietetic study is more difficult and dermal tests are more helpful. The dermal tests also have the advantage of consuming less time.

DERMAL TESTS

The dermal tests depend upon observing the reaction of the skin to various purified proteins. While in very sensitive persons, the mere application of certain proteins to the skin surface may produce a reaction, it is necessary to get more definite information, to introduce the protein through the outer layers of the skin. This has been accomplished in two ways. The first method consisted of scarifying the skin, rubbing an alkalinized solution of protein into the scarified area, and observing the reaction, the development of an urticarial wheal about the area indicating sensitization. The other method, which in recent years has entirely supplanted the first, consists of the endermic (intradermic) injection, by means of a hypodermic needle, of sterile solutions of

purified proteins, a positive reaction consisting of the development of an urticarial wheal with pseudopod-like projections from its edges.

The purified proteins may be very simply prepared in any well equipped laboratory or may now be obtained from a number of reliable pharmaceutical houses. As many as two hundred proteins are used by some clinicians in testing for sensitization. In most of my cases the proteins were prepared and applied by Dr. R. H. Bennett, of Brooklyn. It must be remembered that not all persons with gastrointestinal sensitization will show an equal degree of skin sensitization, so that mild or even absent skin reactions do not necessarily indicate mild or absent gastrointestinal sensitiveness. The dietetic test is the final criterion of gastrointestinal sensitization.

TREATMENT

The treatment of gastrointestinal allergy consists of treating the patient during an allergic reaction and of using measures to prevent future attacks. With the onset of the reaction, it is desirable to remove as much as possible of the offending protein from the gastrointestinal tract by lavage or induced vomiting and by catharsis. For the actual relief of symptoms, adrenalin chloride solution, 1 to 1,000, given intramuscularly or sublingually in ten to fifteen drop doses, will frequently act with great rapidity. Pituitrin is said to produce a later but more lasting effect. Calcium salts in large doses, such as a heaping teaspoonful (eight grams) of calcium lactate, will enhance and prolong the effect of the adrenalin. The calcium should, of course, be well diluted with water. Belladonna or atropine occasionally relieves the spasms, but these drugs are not to be compared with adrenalin in this respect. The reason for this effect of adrenalin is not known, but its efficacy in asthma, urticaria and other allergic manifestations has long been recognized.

To prevent allergic reactions, the only certain method of treatment is to remove the offending protein or proteins from the diet. This is easily accomplished in the case of foods which are only occasionally used in the patient's diet, such as berries, condiments, shellfish or even ordinary meats, fruits and vegetables or beverages. But where the patient is sensitized to such common articles of food as milk, egg or wheat, it is not only a great hardship, but practically an impossibility, to follow a diet with these proteins eliminated. In these cases desensitization must be attempted.

DESENSITIZATION

Desensitization may be accomplished in two ways. The specific method consists of either the oral or hypodermic administration of increasing doses of the offending proteins. In gastrointestinal allergy the oral method is to be preferred. In some cases hypodermic injections may be given at first and then followed up with increasing doses by mouth, but I have found the oral method entirely satisfactory. In the case of milk, the first dose by mouth should be one drop a day, which should be increased at first a drop at a time and then more rapidly as the daily dose becomes larger. Within a month a patient can thus be brought to a point where sufficient milk may be taken to make beverages and cereals palatable, or to permit of the taking of small quantities of desserts containing milk. Egg must be started in much smaller doses, many of the failures in oral desensitization being due to too large an initial dose. I have usually started with a teaspoonful of a solution of one drop of beaten egg in a glass of water, and have gradually reached a point where a whole egg a day could be tolerated. In the case of wheat, the flour may be made into a solution by boiling, and similarly administered. It is useless to desensitize a patient to occasional or seasonal foods, as it is a fact that unless the protein is taken daily thereafter, sensitization will rapidly recur. It is therefore only worth while to desensitize to milk, egg, wheat or potato, all of which may be taken each day without becoming distasteful.

Nonspecific desensitization, much heralded, especially in France, while it would be an ideal method if successful, has not in my hands proved to be the panacea it was supposed to be. This method is based on the theory that by the intramuscular or intravenous injection of a foreign protein the resistance of the body to all proteins may be raised. It is essentially the same as nonspecific protein therapy of chronic infections, and consists in the injection of vaccines, peptone solution or other proteins into muscles or veins. The dose may be such as to cause a general reaction—chill and fever—or may be minute, and increased at three or four day intervals until large doses may be given intravenously without general reaction. A general reaction is probably desirable, cases having been reported where complete desensitization to food proteins has been produced by one severe reaction after an intravenous dose of colon bacillus vaccine. My experience with the nonspecific method has been disappointing, the patients getting only temporary relief following the injections, even in cases where fifteen or twenty injections have been used, with the dose of peptone up to 2.5 c. c. of five per cent. solution intravenously.

ENDOCRINES

Endocrine therapy has been tried, and in some cases has been found to be successful. The continued administration of adrenal or pituitary extracts to prevent allergic attacks is not satisfactory nor advisable. Parathyroid therapy, using doses of one tenth grain of the gland, has in some cases seemed of value, especially where combined with the administration of large doses of calcium. I have used as much as a heaping teaspoonful (8 grams) of calcium lactate, well diluted with water, three times daily.

CASE REPORTS

Case I.—M. O., female, a housemaid, twenty-nine years old, nineteen years previously had had severe epigastric pain attacks every few months for several years, each attack lasting a few hours. Subsequently she had noises in her ears and later pains in her joints and neck. Three years previously she had had a few recurrent attacks of the old pains, very severe and associated with a rash, vomiting and dizziness, and followed by a brief diarrheal period. After nine months of these attacks appendectomy had been performed, and subsequent to this she had an attack of urticaria. She had then had a few abscessed teeth and badly diseased tonsils removed. She had then become constipated and had begun to have attacks of obstipation lasting three days and associated with

vomiting. The anal sphincter had been stretched for spasm and this had been followed by a cholecystectomy. The surgeon reported that the colon had looked thickened and diseased at operation, and suggested its removal if symptoms persisted. Following this operation severe attacks of epigastric pain, vomiting, and dizziness, accompanied by diarrhea, occurred. Examination showed nothing abnormal except eight pulpless teeth, which were removed at once. No other focal infections were found after thorough study by experts. Blood, urine and stool examinations were negative. Gastric analysis (fractional) showed a reflex continued secretion, good motility, and blood in all specimens. X rays were negative except for evidences of moderate gallbladder adhesions.

During the study of this case angioneurotic edema of the face and neck occurred coincident with several very severe pain attacks, and both symptoms were promptly relieved by adrenalin. Skin sensitization tests, confirmed by repeated dietetic tests, showed positive reactions to apple, peach, plum, milk, cheese, eggs and oysters. Withdrawal of these foods from the diet resulted in a cessation of the attacks, but nonspecific protein desensitization was attempted, twelve intravenous injections of peptone, in increasing doses up to two c. c., being given. This treatment resulted in some general improvement, but did not provide immunity to the offending proteins. Later oral desensitization to milk gave marked relief and the patient is now free from attacks and is taking up training as a nurse.

Case II.—E. J., female, housewife, forty-five years old, first seen by me in 1917, had been well until an attack of diphtheria eight years before had left her with a weakened heart. For five years she had had frequent attacks of severe abdominal cramps, usually associated with diarrhea, and milder attacks of gas, a moving feeling in the abdomen and occasional canker sores. Examination showed nothing abnormal beyond a slight nasal obstruction, small reddened tonsils and canker sores. Laboratory and x ray findings were negative, but food protein skin tests showed marked sensitization to peas and mild to milk. Dietetic study also revealed sensitization to grapes and spinach. Oral desensitization to milk and avoidance of the other foods resulted in relief of symptoms.

This patient has been seen off and on ever since 1917, has had a hysterectomy for fibroids, dental extractions and tonsillectomy for chronic gastrointestinal infection and chronic arthritis, and still gets gastrointestinal symptoms, but no diarrhea, from peas, cheese and grapes.

CONCLUSIONS

1. Gastrointestinal manifestations of food allergy are frequently overlooked and patients uselessly subjected to multiple operations.

2. Gastrointestinal manifestations are due to direct irritation of the mucosa or are part of a general reaction.

3. The diagnosis is made by a study of the history and by dietetic and dermal tests.

4. The treatment consists of the alleviation of the severity of the attacks and the withdrawal of or desensitization against the offending proteins.

88 Sixth Avenue.

The report of another case and a bibliography will appear in the author's reprints.

Cases in Which the Test for Pancreatic Efficiency Has Been of Clinical Assistance

Clinical Report No. 1

ANTHONY BASSLER, M.D.
and J. RAYMOND LUTZ, M.D.
New York

A test for estimating the enzyme activity of pancreatic juice (1) was suggested by one of us, which is accurate, inexpensive and easy to perform. By using the A fraction of a socalled medical bile aspiration, a five per cent. peptone solution being used as the stimulant, a knowledge of the storage factor of the gland and its enzyme potency can be obtained for diagnostic purposes. A few cases are presented in which we feel it furnished us with clinical data worthy of mention. The cases are described briefly, all of the irrelevant points in the history and examination being omitted.

Low grade pancreatitis from chronic gastroduodenitis. Value of the pancreatic test in suggesting therapy.

Case I.—Mrs. A. L. The patient was referred by Dr. J. T. Travers, New York, on May 12, 1924. She was a housewife, aged thirty-four, married, and had two children. Her family and personal histories were not significant, except that the gallbladder and appendix were removed three years ago after a year of symptoms of indigestion. Tissue diagnosis was chronic cholecystitis and chronic appendicitis.

Her present illness began after the birth of her last child four years ago, with belching, a metallic taste, coated tongue, and abdominal distress after meals (usually two or three hours) which was sometimes painful and radiated into the back. She ate little because of this distress. She said that for one year after the operation she was distinctly better and then all the former symptoms returned.

The report of the x ray examination by Dr. Travers showed no six hour gastric stasis, a hypertonic stomach, no fixation, and a tender duodenum; a diagnosis of postoperative adhesions was made. He also reported albumin in the urine. The physical

findings were separation and distortion of the teeth suggestive of pituitary disturbance, dry and badly coated tongue, and a normal pelvis. The patient was well nourished. Laboratory findings: Ewald test meal, 20 c. c. return, free HCl 0, total acidity 20, mucus xx, slight free blood, negative Boas-Oppler, lactic acid and Wolff-Junghans. Urine negative except for a trace of albumin. Bile aspiration, A fraction, color normal, clear, mucus x, pus x, Bassler test 6 units. Diagnosis, hypopituitary type, chronic gastritis and duodenitis, hypopancreorrhea (2). Treatment, anachlorhydric diet, enteric coated capsules each containing one gr. of pancreatin and soda bicarbonate.

Progress notes: Treatment began on May 16th and on May 26th the patient reported relief of all symptoms except that the capsules tended to constipate her. This was relieved by an occasional alkaline saline purgative. She was discharged on June 5th and has felt well since.

Comment: This case suggests that not much was wrong with the gall tract and that the chronic duodenitis caused the hypopancreorrhea by some interference with the gland's function. While it is well known that an achylia is often improved by this type of diet and alkaline pancreatic powders, usually in achylia the pancreas is efficient until very late. What the Bassler test proved, however, was that a pancreas may become "low" in these instances and in giving these powders and using the test one can prove whether it is only functional or organic.

Chronic cholecystitis in which the low pancreatic efficiency in the test suggested disorder of the pancreas and a discussion of the advisability of an operation.

Case II.—Mrs. J. H. N. The patient was referred on October 14, 1924; she was sixty years of age, married, no children. Her family history was negative, her father and mother died at advanced old age. Her personal history was not significant. She said she had had attacks of indigestion for about ten years off and on. After eating, the upper abdomen became distended and there was a marked sense of weight and pressure. These attacks were accompanied by excessive belching of gas, and were present in the midmeal intervals. At times, independent of meals or the presence of indigestion, she had dizzy spells. She said that since the illness of her husband about four months before, the gastric distress became much worse, which she thought was due to mental and physical strain. She had practically no desire for food, her feet and hands were constantly cold, she slept fitfully, and had lost about ten pounds in weight in the last six months. She was moderately constipated.

Physical examination showed a poor condition of teeth but no oral sepsis. The blood pressure was 140/100, and there was a distinct arteriosclerosis. The liver was stiff and large, mainly on the left side, the surface being smooth and the edge not palpable. There was tenderness on pressure in the epigastric region, this being exquisite over the gallbladder. X ray examination was negative as to stones and visibility of the gallbladder, and the other matters not significant. The urine contained a slight amount of albumin and a few granular casts. The bile aspiration on October 16th showed: A fraction, 30 c. c. return, yellow, clear, mucus xx, no pus, Bassler test six units; B fraction, 70 c. c. return, brownish, clear, mucus xx, pus xxx, a few cholesterin crystals, and no bacteria of note; C fraction, 20 c. c., yellow, clear, no mucus, no pus.

The diagnosis made was slight grade of chronic cholecystitis, hypopancreorrhea due to arteriosclerosis of the pancreatic arteries, and a slight grade of arteriosclerotic kidneys, with a neurosis. Treatment consisted of an arteriosclerotic diet of no meat, eggs, fish or fowl, ninety grams of vegetable protein a day were permitted; with a limited amount of foods and generous in selection; small doses of iodides; the gallbladder pills to be mentioned later; gradually increased amounts of walking; hot packs twice a week; a citric acid, soda bicarbonate, and pancreatic tablet after meals. No bile aspirations were done as treatment, as the patient said that the first tubing "knocked her out" for several days, probably because she was so nervous at the time, and on the second attempt this was repeated with difficulty.

Progress: Subsequent history notes through October and November showed modifications in treatment here and there. A tonic consisting of a tincture nux vomica and glycerophosphates was added in mid November and on December 2d the patient said that she felt perfectly well. She showed distinct improvement in her appearance and manner, the tenderness over the gallbladder had markedly subsided, but the liver was not changed. A Bassler test was done on December 18th, with a reading of six units.

Comment: The low pancreatic reading at the first examination in the presence of marked arteriosclerosis strongly suggested a hypopancreorrhea from diseased vessels in the pancreas for which no definite result could be obtained from operation in the advanced state of the vessel disorder, even if a cholecystectomy were done. The marked condition in the liver also led to the same conclusion. There was a moderate degree of general improvement on medical treatment but the pancreatic test showed that the low pancreatic function was permanent because of the diseased vessels.

The following is a case of hypopancreorrhea due to gallbladder pathology, with stiffening of the pancreas found at operation. Test readings were made before and six months after operation.

Case III.—Mrs. J. M. McA. The patient was referred by Dr. A. N. Lyons, January 17, 1924. She was forty-seven years of age, married, with three children. The family history was not important. The past history included pneumonia at twenty-two, typhoid at thirty-five; otherwise irrelevant. The present illness was as follows: After her second child was born she began to have an indefinite form of indigestion, which was promptly relieved by a saline cathartic and an occasional dose of sodium bicarbonate. After the birth of her last child, with which there was no digestive distress, she began to have sharp attacks of gas, distention, and distress, usually after meals, but at times independent of them. A constipation lately became more marked, and she was often troubled with a distended feeling in the abdomen, which was relieved by passing gas. This had awakened her at night a number of times, and, although relieved, she could not sleep afterward. Four weeks previously she had an attack of sharp pain

in the centre of the abdomen "under the ribs," requiring morphine for its relief. The next day the pain returned, although milder, and was relieved by an electric pad. Since then there had been a soreness in the upper abdomen and the patient was afraid to eat. She often felt a chilly sensation in the back.

The physical examination showed a large, well nourished woman. The left lobe of the liver was palpable, there was tenderness on pressure in the epigastrium, and perhaps more on the right side than left of the midline. The blood pressure was 147/97. Laboratory examination showed urine negative except for high calcium oxalate crystals; and the feces acid, gassy, with high gram positive double cocci and Bacillus welchii. The Ewald test meal return was 90 c. c.; free HCl, 46; total acidity, 64; combined HCl, 56. The blood chemistry was urea nitrogen 14; sugar, 0.12; creatinin, 1.5; cholesterol, 0.24. The Lyon test corresponded to negative in a diagnostic way. The Bassler test reading was four units. The röntgenographic examination showed a small high stomach, the pyloric end hugging the under surface of the liver, and positive gallstones, seven in number, the gallbladder situated high. Ileal stasis xx; there was spasticity of the colon with fibrillary contractions of the transverse portion.

The treatment was a cholecystectomy. Progress: At operation on January 29, 1924, a gallbladder about normal in capacity and containing stones was removed. The walls were thickened and the organ contained thick dark bile. The sac was attached by adhesions to the under surface of the liver, duodenum, and a dense band near to but not touching the hepatic flexure of the colon. Extensive separation was necessary to remove the organ. The head of the pancreas was definitely thickened and stiff. The patient made rather a stormy recovery in the first ten days, running a temperature for a week; she had much pain for five days, became anuric for two days after the operation, and required catheterization for four subsequent days; a cystitis then developed. However, toward the end of the second week she improved smoothly, and got out of bed on the twenty-fourth day. She left the hospital on the thirty-second day after the operation. The result from the operation was most satisfactory. She was relieved of her digestive symptoms in about two months. On April 3rd, a Bassler test was done that showed eight units, and another on May 19th, which showed fifteen units. An x ray on May 27th showed no ileal stasis, but still some spasticity of the colon. The bowels were regular.

Comment: This is the common enough picture of a long neglected pathological condition of the gallbladder, with stiffening of the pancreas from that pathology, a low unit reading at the time, and a normal unit content about three and a half months after the operation. Evidently the stiffening of the pancreas was reduced (congestion) by the removal of the gallbladder, the organ resuming a normal function. With this the ileal stasis was overcome, the bowel function also improving. The test here proved of value in diagnosing an involvement of the pancreas before operation and its subsidence in a few months.

Two cases of pathological conditions in the gallbladder, showing improvement on medical treatment, are reported herewith.

Case IV.—Mrs. J. A. The patient was referred by Dr. J. F. Donnelly, of Philadelphia, on May 8, 1924. She was a housewife, aged forty-two, married, with three children. The family history was not significant. The personal history was negative with the exception of a cholecystectomy for gallstones four years before, by Dr. Thorek, of Chicago. The present illness began as follows: After a cholecystectomy was performed the symptoms present before and at the time of the operation continued, growing gradually more pronounced. About one year ago a rather typical ulcer syndrome began, which was now quite characteristic in all its features. About three months before this, the pain became continuous, was more marked two hours after a meal, but was not relieved on taking food or alkalies. The deduction from an x ray examination made about two months ago was the definite diagnosis of ulcer, and operation was advised.

Physical examination was essentially negative, except that the pupils were contracted and fixed, the mucous membranes were paler than normal, and there was a tenderness on deep pressure in the left inguinal region, also a generalized tenderness on deep pressure up and down the right abdomen. The laboratory examination showed, Ewald test meal return, 50 c. c.; free HCl, 5°; combined HCl, 15°; total acidity, 38°; otherwise normal. Blood hemoglobin, 64 per cent.; red and white blood cells, normal. Bile aspiration done on May 15th produced A fraction, 95 c. c., yellow, turbid, mucus xx, pus xx, Bassler test reading of seven units; B fraction, 65 c. c., darker yellow, clear, mucus xxx, pus xxxx, heavy pure culture of staphylococcus; C fraction not determinable. The urine and feces were negative. Deductions from an x ray examination were gastric hypermotility, gastrospasm, ileal stasis xxxx, otherwise negative.

The diagnosis was infective cholangitis and hypopancreorrhea. The treatment consisted of hypercholesterinemic diet given May 20th, together with Carlsbad salts in the morning, soda bicarbonate and pancreatin, one grain, three times a day after meals, autogenous staphylococcus vaccine, a daily walk of three miles, medical bile aspirations of alternate peptone and magnesium sulphate solution stimulations every second day, that is, each stimulant every fourth day. Progress: There was a steady subsistence of symptoms; all pain was relieved in the second week. There was an improvement in the bile fractions as to mucus, pus, and bacteria. The Bassler test at subsequent times showed in units as follows: 7, 7, 9, 12, 10, 12, 14, 16, 16. On June 19th the bile aspirations were stopped and monthly bile aspiration since showed marked improvement with high normal pancreatic readings. A few staphylococci continued in the B fraction or what was judged to correspond to it. The medication was stopped after the ninth day from the beginning of the treatment, and a short run of organic iron tonic was given for two weeks. At the last note, January 23, 1925, the patient reported herself perfectly well, still taking the walks, not following the diet, and taking Carlsbad salts about once each week. The vaccine was discontinued in the tenth week from the beginning of the treatment.

Comment: This case suggests that a low pancreatic

activity can and often does give symptoms of gallbladder pathology. In our records, fifty-two per cent. of cholecystectomies done where no stones are present return with essentially the same symptoms as before operation. This is based on a group of 319 cases. Adhesions and other conditions not diagnosed or impossible of good treatment, no doubt account for some cases, but in the majority a deficient pancreatic activity is the important factor in their production. The steady bile drainages here were, no doubt, helpful and the other medical treatment assisted. We believe that the drainages rather than the vaccine were of most assistance in diminishing the infection because the improvement started long before the vaccine could have brought any improvement and the staphylococci continue present in the bile. Since more cases of "stiffening of the head of the pancreas" are present in cholecystitis without stones than in instances of cholelithiasis it is probable that this condition of the gland is due more to infection of the ducts and duodenum than the gall sac itself. It seems logical to believe, although no operation was done, that at least a congestive condition of the head of the pancreas existed and that with its improvement from the treatment the head of the gland, which makes up two thirds of its bulk, took on a more normal function with a rise in the pancreatic efficiency and a marked improvement in the case which the Bassler test could prove throughout the course of treatment.

Case V.—Mrs. E. G. The patient was seen March 26, 1924. She was a widow, with no children, a dressmaker. Her family history was not significant. Her personal history consisted of an inflammation of the bowels twenty years before, following the removal of a tumor, nature unknown. The patient was at the time of the visit fifty-five years old, and she had menstruated regularly up to seven years before. Fifteen years before she had several attacks of pain in the epigastrium, which were diagnosed as gallstones. She went to Carlsbad where she stated she was cured. For many years she had attacks of vague pain in the upper right abdomen, and had been unable to take much food without great distress. For the past year she had not eaten any solid food, and could only tolerate milk within the last six weeks. She was constipated and nervous and troubled with gas in the stomach. The physical examination disclosed an asthenic type of woman with hypertrophied tonsils from which streptococci were cultured, considerable crossed sex characteristics, and a marked tenderness on pressure over the gallbladder. The x ray examination showed the presence of negative gallstones, with marked tenderness on pressure over the gallbladder.

The laboratory reported that the urine and stool were negative. A bile aspiration, May 1, 1924, showed A fraction 120 c. c., golden yellow, clear, mucus xxx, pus xxx, Bassler test two units of pancreatic efficiency; B fraction 180 c. c., light yellow, turbid, mucus xxx, pus xxx and clumps of bilirubin. The diagnosis was cholelithiasis, hypopancreorrhea due to stiffening of the head of the pancreas from the gallbladder disease. Operation was refused, and treatment was given in a sanatorium for two weeks with continuous gall duct drainage, the stimuli used being magnesium sulphate, olive oil, dilute HCl and peptone solutions. The daily output of fluid was always satisfactory. After the tube had been out for a week, a bile aspiration was done, giving A fraction 50 c. c., light yellow, clear, mucus x, no pus cells, Bassler test eight units; B fraction 95 c. c., golden yellow, clear, mucus x, few pus cells. Bile aspirations were kept up for ten weeks, twice weekly and once a week until October 26th. In all of these the pancreatic unit figure was eight. Additional treatments during the interval were Carlsbad salts and hypercholesteremic diet.

Progress: On June 19th the patient reported herself as well, and as not having had any symptoms after the second week out of bed. This has continued up to the present; she has gained twelve pounds in weight since treatment.

Comment: This case seemingly proves that, even with gallstones present and a long history of them, medical drainage of the bile passages may be helpful and beneficial in restoration of the pancreatic condition due to stiffening of the head of the gland from their presence or an attendant infection. The fact that the stones continue present probably accounts for not obtaining a higher unit content than eight which may be designated as the low normal, or it may be due to permanent sclerotic changes due to the long duration of the primary biliary tract disease which, according to the history, extended over at least fifteen years.

The following case is of chronic cholecystitis getting worse during treatment, warranting cholecystectomy and the pancreatic test as a guide in judging this.

Case VI.—Mrs. A. M. C. The patient was referred by Dr. Adams, of Whitestone, Long Island, September 12, 1924; widow, aged sixty-two, no children. Family and personal histories were negative. The present illness began about February, 1923, when foods commenced to cause distress; this gradually grew worse, when a pain developed in the upper right abdomen. The patient at first thought she might have strained her side, because the pain came on quickly; she said she thought she had a fever for a few days. The soreness of the right side continuing and the gastric distress becoming worse, Dr. Adams considered the possibility of gallstones. An x ray examination was made in June, which was negative as to proving the presence of gallstones. The patient had had a nocturia two to three for years, but many examinations of the urine did not prove anything.

Physical examination showed a well nourished and proportioned woman, blood pressure 140/90. The examination was negative with the exception of a marked stiffening of both lobes of the liver and a distinct tenderness on pressure in the median fissure. The laboratory examinations showed negative urine, normal renal efficiency test, and the following bile and pancreatic tests: September 15th, A fraction 20 c. c., light yellow, cloudy, mucus xx, pus xx, and Bassler test twelve units; B fraction, 70 c. c., dark brown, cloudy, mucus xx, pus xx; C fraction 60 c. c., light yellow, cloudy, mucus xx, pus xx. The diagnosis was chronic cholecystitis, perhaps with stones, and secondary fibrosis of the liver. Operation was refused.

(*To be concluded*)

Cholecystoduodenostomy by Nature

EDWARD A. HERR, A. B. M. D.
Waterbury, Conn.

The passage of large gallstones per rectum has been reported at various phases in the history of biliary tract surgery. Recently a report by Gordon (1) and later one by Niles (2) stimulated my interest in this phenomenon of nature.

The literature on gallstones brings out some very interesting facts. Intestinal obstruction not infrequently occurs from large calculi escaping from the gallbladder and lodging in the lumen of the intestine. Courvoisier's statistics of fifty-two cases gives impaction in the duodenum and jejunum in 21.4 per cent.; in the ileum in 65.2 per cent.; in the ileocecal valve 10 per cent. and in the sigmoid flexure in 2.4 per cent.

In Robert's case, reported in 1903, a calculus of unusual dimensions was removed from the ileum This measured four and a half by three and a half inches in circumference. An even larger calculus than this was removed by Baildon in 1915, measuring five and a half inches in circumference.

Statistics from various sources (3) show that from two to four per cent. of the cases of intestinal obstruction are due to large gallstones. In some cases the calculus may be felt through the abdominal wall as a round or slightly oblong hard mass, devoid of tenderness and in any region of the abdomen or the pelvis, depending upon in what part it is lodged.

FIG. 1.—Gallstones passed by patient in Case I

Gallstones too large to pass through the cystic duct may be accompanied by inflammation of the gallbladder and promote ulceration or peritonitis (4). Not infrequently they will rupture through into the intestine. Deaver states that, "in a large majority of cases the calculus enters the intestinal tract through a fistulous opening between the gallbladder and the duodenum."

The case I shall report is similar to that reported by Gordon but differs in the number of large gallstones passed.

CASE I.—On October 7, 1921, I was called in to attend Mrs. C. S. who was in a typical gallstone colic attack, which had its onset three days previously with constipation, nausea, vomiting and severe abdominal pains in the upper right quadrant. The pain had increased in severity and was localized in the region of the gallbladder and was accompanied by epigastric distress and referred pain to the right scapula. There was no fever.

The patient was forty-one years of age. Menses began at twelve years, regular twenty-eighth day type, three days' duration, scanty flow, and no pain. She had married at twenty-eight and was never pregnant. She had grippe at thirty-four years, with complete recovery and no sequelæ. At thirty years hyperchlorhydria started and the first attack of gallstone colic occurred when she was thirty-four years old. Recurrent attacks of moderate severity occurred twice yearly up to present complaint. She had otherwise always been strong and performed her daily household duties for herself and husband regularly. She had always been a hearty eater, indulged in alcoholic liquors moderately, was regular in habits of sleep, lived in a sanitary environment, but was subject to attacks of nervousness.

Physical examination showed a female, weight 70.5 kilos, height 162 cm., well nourished and corpulent, in severe abdominal pain. The sclera was moderately jaundiced, skin slightly jaundiced, facies worried. Respirations were increased and restricted but the pulmonary sounds were negative. Cardiac sounds were clear and distinct and of good quality. The abdomen was round, corpulent and distended. There was tenderness over the epigastrium and well localized tenderness over the gallbladder, with moderate right rectus rigidity. There was dullness in the upper right quadrant and tympany through the remainder of the abdomen. Temperature was 99°, pulse 90, and respirations 26.

The patient was told of the necessity of an operation but chose to remain home until the attack had subsided. The usual treatment was instituted and gradual improvement followed, interrupted by irregular abdominal pains. On December 1st two large gallstones were passed, per rectum, and on December 2d two more were passed, followed by six more up to December 9th. Since then she has enjoyed good health and has been free of all gallbladder symptoms.

The stones, as shown in Fig. 1, were of the calcium cholesterin type and were weighed three years and two months after they were passed by rectum. In the order of their arrangement in the illustration their weights in grains were one hundred and twenty-four, fifty-four, fifty-four, forty-nine, forty-seven, thirty-nine, thirty-five, one and a half, one, one, and three quarters. Undoubtedly these would have shown a higher weight if weighed immediately.

It is quite likely there was a chronic low grade of cholecystitis present in this case at the time of the acute attack and the abdominal straining augmented by peristalsis caused an ulceration into the duodenum resulting in a fistula through which the calculi passed, and owing to their size were delayed in their passage through the intestine. Assisted by the subsequent adhesions a natural cholecystoduodenostomy resulted which accounts for the drainage of the gallbladder and the relief of symptoms.

Lesions of the Gallbladder

JOHN B. HAEBERLIN, M.D.
Chicago

The treatment of infections and pathological conditions of the biliary system cannot by any means be called a closed chapter in medicine. While numerous papers have been published of pioneer work in this field during the past twenty-five years, as yet, there is no unanimity of opinion among physicians regarding treatment, and, particularly, the proper evaluation of medical and surgical procedures.

The purpose of this paper is to analyze briefly the various procedures advocated in the treatment of lesions of the biliary system, and to attempt to evaluate these means based on rational anatomical, physiological, and pathological grounds.

Even at the risk of repeating facts known to many, a brief résumé of the anatomy, physiology and pathology of the gallbladder is here given in order that a clearer conception of the pathology of gallbladder infections and their clinical symptoms may be understood. While the modern trend of medical teaching today is to limit or disregard the old fashioned drilling in the fundamentals of anatomy and allied subjects, I cannot but feel that this is a serious error in our teaching, with the result that many medical men cannot properly interpret symptoms, signs, and findings of gallbladder infections.

Gall tract disease was known to the ancients. It was mentioned in the literature of the Middle Ages and was believed to be the cause of many obnoxious humors of the body. The first mention of gallstones was made by the Greek physician Trallianus Alexander, who wrote about the fifth century A. D., but this excellent description was lost for over a thousand years and was not republished until 1548. Gallstones were called "dried up humors." The next reference was made in 900 A. D., four centuries later, by Rhazes, the Arabian physician who described gallstones in the ox.

Like the uterus, gallstones were considered the cause of epilepsy. It was not until 1507 that we have the first accurate account of gallstones in a paper by the celebrated Italian physician Benivenius, entitled "On the Hidden Causes of Disease." Can we not with almost the same modesty apply this title to the many recent papers on biliary lesions?

During the eighteenth century there were less than twenty contributions to our knowledge of gallbladder disease. In 1725 St. Andrews was the first to draw a distinction between obstructive and hemolytic jaundice.

It can readily be seen that our present knowledge of the cause and effects of gall tract disease is closely allied to the development of the surgical era of medical history. Credit for most of what we more recently have learned is due to the writings of Pasteur, Ehrlich, Nothnagel, Naunyn, Kehr, Mayo-Robson, Weil, Moynihan, Bland-Sutton, Chiari, Banti, Pavlov, and Rolleston. Of the more recent contributors we must mention Musser, Herter, Ewald, Kelly, Mayo, Brewer, Deaver, Meltzer, Smithies and a host of physiologists, röntgenologists and clinicians.

ANATOMY AND PHYSIOLOGY.

Only the important points of the anatomy, embryology and physiology are cited here to refresh our memories of these facts. It is remembered that the digestive tract at first is just a straight tube. From this, two analagen or buddings are formed, which forms the future lungs and the third and fourth are the analagen which form the future liver, part of the pancreas and the bile ducts.

The two liver analagens unite and together form the right and left lobes of the liver, with the two ducts which as a rule unite in a common duct from which the cystic duct later develops. The gallbladder is the reservoir for the bile; it is a conical or pearshaped musculomembranous sac, lodged in a fossa on the under surface of the liver, fixed by connective tissue, and extending from front to back, obliquely. Its length is three to four inches, its breadth one inch or more at its widest part, and it holds from thirty to forty c. c. It must also be borne in mind that the liver secretion is from 1000 to 1500 c. c. and it can readily be seen that only a very small amount of the bile is present in the gallbladder if it was only a simple reservoir, but upon analysis the bile in the gallbladder as compared with that secreted by the liver has been found to have a concentration from six to eight times, in addition to an increase of mucus. This, fundamentally, is one of the principal reasons for the development of pathological conditions in the gallbladder.

It is divided into fundus, body and neck—the fundus or broadest part directed downward, forward, and to the right and at times projecting below the edge of the liver. This anatomical fact is of clinical importance in the differential diagnosis of hydropic gallbladder and kidney enlargements. During the respiratory excursion the amount of motion and direction of these two organs varies.

The body and neck are directed upward, backward, and to the left, and the neck is at a slightly higher level than the lowest point of the fundus—and thus the direction of the bile is away from, rather than towards the outlet. It is selfevident that this leads to a tendency to stagnation of bile with the resultant pathological infections and stone formations.

The upper surface of the gallbladder in the majority of instances is attached to the liver by connective tissue, bloodvessels, and lymphatics, but not infrequently the whole organ is completely invested with a serous or peritoneal coat so that we have a gallbladder attached by a "mesentery."

The cystic duct is the smallest of the three biliary ducts, measuring one and one half inches in length and less than one quarter inch in width, and passes obliquely downwards and toward the left to join the hepatic duct and form the common duct. It is

in the gastrohepatic omentum in front of the portal vein with the hepatic artery lying at its side.

The common duct—the largest of the three ducts is the common excretory duct of the liver and gallbladder—is three inches in length, about the size of a goose quill, and in ninety per cent. of cases has a common point of entrance in the duodenum with the pancreatic duct. This conical cavity, formed by fusion of the two ducts, is known as the ampoule of Vater. It averages about four tenths of an inch in length. If fusion of the ducts does not take place there is no ampoule of Vater. The orifices then open upon the summit of a papilla. It should also be remembered that there is a sphincteric arrangement of circular, muscular fibres—sphincter of Odii—which may be spastic at times and give rise to gallbladder symptoms.

The walls of the ducts and gallbladder consist of three coats, an exterior or serous coat, a muscular, and a mucous coat. The mucosa of the gallbladder is generally tinged with yellowish brown color and is everywhere elevated into minute rugæ by the union of which numerous meshes are formed. The depressed intervening spaces have a polygonal outline, smaller at the fundus and neck.

Opposite the neck of the gallbladder the mucous membrane projects inward as oblique folds or plications which somewhat resemble valves. (Heister). Here, too, definite sinuses are present in about twenty-five per cent. of gallbladders which may not only penetrate the mucosa but may even extend through the muscular coat to the peritoneal surface. This accounts for the presence of small calculi, present at times, subperitoneally. Mucous glands may be present in this coat as well as diffuse lymphoid tissue, and it should be emphasized that many authorities do not consider these as true glandular structures.

The mucosa consists of a single layer of high columnar epithelium which extends to and becomes continuous with the mucosa of the duodenum. Its blood supply comes through the cystic artery, a branch of the hepatic, and by branches from the hepatic arterioles within the liver substance overlying it. The cystic artery runs parallel with the cystic duct and at its neck divides into two branches. This accounts for the profuse hemorrhage often encountered when the gallbladder is dissected from its bed from above downwards. The cystic veins open into the right branch of the portal vein.

The nerves of the gallbladder come from the celiac plexus, from the left pneumogastric, branches from the phrenic derived from the fourth cervical. This accounts for pain referred to the right shoulder in gallbladder disease through the supraacromial nerve —also a branch of the fourth cervical.

The gallbladder is supplied with very rich lymphatic plexuses. There is one set of lymphatics just beneath the mucosa in which collections of lymphoid tissue is present. There is a second group in the muscular layer and another group beneath the peritoneal layer.

All the lymphatics converge at the cystic duct—some passing to the lymphatics of the pancreas, some to the under surface of the liver and some to the anterior surface of the liver.

It can readily be appreciated from the few outstanding points emphasized, that a thorough knowledge of the anatomy of the biliary system is absolutely necessary to interpret fully clinical findings in gall tract disease.

BACTERIOLOGY AND PATHOLOGY

No attempt will be made to discuss the pathology and bacteriology of the gall tract lesions except to reiterate that the same processes occur in the gallbladder as found in the appendix and other organs. All types of bacteria have been isolated from the biliary ducts and gallbladder, especially the pyogenic organisms and notoriously the typhoid bacilli.

CLINICAL SIDE OF LESIONS OF THE GALLBLADDER

The forms of cholecystitis are numerous and constitute a progressive pathological series passing one into another. The clinical types are:

A. Acute.
   1. Catarrhal cholecystitis (membranous).
   2. Acute nonsuppurative cholecystitis.
   3. Suppurative cholecystitis.
B. Chronic cholecystitis.
C. Pericholecystitis.

The lesions of benign and malignant tumors of the gallbladder will not be taken up.

SYMPTOMS

No matter what its pathology, the severity of the symptoms varies with the degree of inflammation. The onset may be sudden or more gradual, following an indiscretion in diet, food poisoning, colds, exhaustion, and the like.

Local signs are due to two factors:: 1, infection, which spells peritonitis, and 2, overdistention, which means obstruction.

There are signs of local peritonitis in the right upper quadrant of the abdomen—pain, tenderness, and defensive rigidity of muscles. In addition to dull continuous pain there may be paroxysmal attacks of biliary colic, due to an obstructive process, which may mean stone or catarrhal obstruction. This pain may be referred to the right iliac fossa, stomach or back; the gallbladder may be palpable or even visable, always tender. Vomiting is common; fever present; leucocytes are increased. Respiration is restricted and jerky when deep; jaundice may occur due to extension into bile ducts; enlargement of liver due to concomitant infection is present. The attack, if left alone, subsides in ten to fourteen days, leaving a predisposed gallbladder awaiting some future attack.

DIAGNOSIS

The diagnosis may be easy or difficult, even impossible sometimes. There is a method of draining the gallbladder by means of a duodenal tube; drain the bile and then make microscopic and bacteriological analyses.

The separation of cholecystitis and gallstones is of only relative importance; practically all cases of gallstones have an associated cholecystitis, where as in many cases of cholecystitis there are no stones. In gallstone colic pain is more excruciating, whereas in cholecystitis there is evidence of local peritonitis.

In some cases it is difficult to differentiate from appendicitis; the tumor mass in gallbladder disease extends downward, in appendicitis upward. Res-

piratory excursion is greater in gallbladder disease. Sometimes differentiation is impossible as they are both present.

Right sided acute pyelitis may mask cholecystitis, in which case pyuria would be present, with other secondary findings.

SYMPTOMS OF CHRONIC CHOLECYSTITIS

There may be recurring attacks of biliary colic. The gallbladder may be tender, or it may be so tucked under the liver as to be impossible of palpation. It is nevertheless tender if we can get to it. In chronic cholecystitis, gallstones are so commonly associated that it is at times impossible to differentiate. In some cases, we have pericholecystitis adhesions, which give us only gastric symptoms.

Dyspepsia due to chronic cholecystitis may resemble that due to chronic appendicitis. In the absence of gallbladder findings the diagnosis is most difficult. (The hydrochloric acid in the gastric juice is diminished, whereas in dyspepsias of gastric origin the acid is increased.) If, however, with dyspepsia there are symptoms of toxic or microbic absorption, such as arthritis, phlebitis, neuritis, or myocarditis, we should be doubly prepared to find chronic disease of the gallbladder.

In chronic cholecystitis there may be a gallbladder that attaches to the surrounding viscera, as the stomach, colon, intestines. It may produce fistula (following ulceration), local abscesses, general peritonitis, diverticula and hemorrhage. In about four per cent. of the cases primary carcinoma supervenes. Of rather infrequent occurrence in chronic cholecystitis is a condition of "white bile."

WHITE BILE

White bile has been a puzzle to many operators. We nearly all agree that when present it indicates greater operative risk. Its cause is surmised but unknown. Kausch believes it is due to obstruction. There is a secretion of the mucosa of the biliary passages which is greater than resorption, which results in a distention of biliary passages with a gradual rise of pressure. When a certain point is reached the direction of the flow in the liver is reversed, that is, the bile passes back into the lymphatics and bloodvessels, and the mucosa continues to secrete. As a result of a continuation of this process the liquid in the ducts of the biliary passages becomes lighter and lighter and finally colorless.

Judd and Lyon report six hundred and forty-nine operations on common and hepatic ducts, in nineteen of which there was white bile—nine, obstruction from stone in common duct; six, trauma from previous cholecystectomy; two, cancerous; two, pancreatitis.

CHOLELITHIASIS

The formation of gallstones may be aseptic or infective.

Aseptic gallstones are due to a precipitation of cholesterin present in excess in the gallbladder, the normal amount being twenty to eighty mgm. to one hundred c.c. of bile and one hundred and thirty to one hundred and eighty mgm. to one hundred c.c. of blood. Cholesterol oleate is excreted into the gallbladder and the oleic radical split off and reabsorbed by the mucosa. A single pure cholesterin calculus is thus formed without any causal inflammation.

Infective stones are due to a mild grade of inflammation of the mucous membrane of the gallbladder. As a result there is an excessive liberation of cholesterin from the mucosa of the gallbladder, the bilirubin and calcium acting as a cement. The cholesterin content of the bile varies with the cholesterin content of blood, an increase or decrease in the blood causing a similar change in the cholesterin content in the bile. When infection occurs in a person with hypercholesterinemia and high cholesterin content in the bile, the condition for calculus formation is doubly assured.

The microorganisms causing a lithogenic catarrh are especially the typhoid, paratyphoid, colon and streptococcus (nonhemolyticus). This is thought by some to be the most important troublemaker. Other organisms are the pneumococcus, pneumobacillus, streptococcus hemolyticus, staphylococcus, micrococcus, Bacillus pyocyaneus, Bacillus influenza, and others.

Stagnation of bile is also an essential factor. Wherever stagnation exists there is a condition favoring infection. The anatomical and physical conditions producing stagnation are low fundus of gallbladder, cystic duct being higher than the bile, spiral fold in cystic duct causing retardation, low grade flaccidity of gallbladder wall. The sphincter of Odii, in its relation to diet has been proved to have a marked influence on stagnation.

The following triad of conditions, then, constitutes the acme of perfection in the production of gallstones, namely, high cholesterin content, stagnation of bile, and infection.

TIME ELEMENT IN THE FORMATION OF GALLSTONES

Klivert has produced stones experimentally in ten days. Rolleston and Mignot state that in five to six months a well formed stratified gallstone may be formed. Moynihan reports a case of typhoid fever in which a stone was formed in three weeks. Cameron reports a case in which thirty-eight gallstones were formed in a period of eighty-six days. I have a case in which a gallstone the size of an egg was probably formed in eighteen months.

INCIDENCE OF GALLSTONES

It increases with age. Still reports ten cases during intrauterine life. The female sex is predisposed to the formation of gallstones.

CLINICAL PICTURE OF CHOLELITHIASIS

The manifestation may be grouped as follows: confined to the gallbladder, biliary colic, obstruction of common duct, extensive inflammation to surrounding parts. The symptoms, however, produced by stones are protean and are grouped as follows: Masked or initial symptoms, biliary colic, purely mechanical or aseptic aspects, including intestinal obstruction, inflammatory and infective results, fistulæ.

Masked or initial symptoms.—Obstinate dyspepsia without relief from treatment, often diagnosed as gastralgia or gastritis. This is especially the case when the hydrochloric acid is decreased. Epigastric distress, coming on from thirty to forty-five minutes after meals, caused more especially by the ingestion

of greasy food and relieved by vomiting. Heartburn is very common. All of these symptoms may suggest gastric or duodenal ulcer but in gallstones we have irregularity of symptoms—intervals of dyspepsia which come and go. Epigastric pain is not relieved by taking food.

Biliary colic.—This is due to spasm of the muscular coat of the bile ducts and gallbladder. Large free stones may not produce colic, while typical colic may be produced by inspissated bile. Inflammation and kinking may also produce biliary colic. We also may get typical biliary colic in plumbism, tabes, and hysteria. Pain of biliary colic is usually paroxysmal and one of the most intense known to mankind. The pain may be primarily in the back, to the right of the eighth to eleventh dorsal vertebræ, then spreading to the front to the right hypochondrium, from thence radiating left hypochondrium, umbilicus and hypogastrium, also to the thigh, right arm, and neck. In some cases the pain begins in the epigastrium. The pain usually lasts three to four hours or perhaps only a few minutes. There may be reflex vomiting, flatulent dyspepsia, shivers and rigors, cold clammy perspiration. Fever may or may not be present. Abdominal muscles are rigid and tender, pulse rate normal and small, leucocytosis slight; albuminuria common, glycosuria rare. Indicanuria may or may not be present. Jaundice may or may not occur.

After an attack there are cutaneous hyperesthesia and muscular soreness of abdomen especially over the right hypochondriac area. This may continue for weeks. Chauffard has described eight tender spots existing during the interval between attacks.

In the diagnosis of biliary colic if the classical pains exist, with subsequent calculus in the stool, the diagnosis is certain. In the absence of stone, the diagnosis is not absolute. An acute cholecystitis may exist. In renal colic pains radiate down the testes, and there are frequent urinations and urinary findings. There may be Dietl's crisis and gallstones in the same patient. The appendix should always be considered, as we know there is a concomitant involvement of the appendix in twenty-five per cent. of gallbladder disease, and this is especially difficult when it is high in the abdomen. We must also consider hyperchlorhydria, gastric and duodenal ulcer and in these we have attacks more regular and not so agonizing. The hydrochloric acid is increased. The patient has learned that alkalies bring relief.

In perforation the patient lies quietly, and in biliary colic he writhes in pain. Tabetic crises should be ruled out by eye findings, the absence of the patellar reflex, and other neurogolical findings. In severe mucous colitis the stool findings are significant.

MECHANICAL EFFECTS OF GALLSTONES

1. Stones in the gallbladder rarely give symptoms. (There may be associated cholecystitis). Very rarely it is possible to produce symptoms by pressure.

2. Impaction of stones in cystic duct produces colic and severe vomiting at times. There may be intermittent hydrops, dilated gallbladder or shriveled gallbladder.

3. The mechanical effects of stones in common bile duct include the occurrence of sudden, severe pain. Pain may be absent, however, depending upon the size of the stones, irritation, and spasm. Jaundice is usually present and persistent and as long as calculi remain, but may gradually subside. In exceptional cases there may be obstruction and no jaundice. Spontaneous cure, following discharge of the calculi may occur, but should not be taken into consideration, as waiting sometimes produces an irreparable condition in the liver.

4. Gallstones in the ampulla of Vater may produce an acute hemorrhagic pancreatitis.

5. Mechanical obstruction of the intestines is very rare. Fritz, Barnard and Morestin have collected cases. A small calculus, if angular, may set up a reflex spasm of the bowel and obstruction. In the majority of cases the stones have ulcerated their way from the gallbladder into the duodenum. The patient is usually old. Vomiting is severe, and there is a previous hystory of attacks. Tympanitis is usually absent.

INFLAMMATORY AND INFECTIVE CHANGES DUE TO GALLSTONES

1. In the gallbladder there may be diverticula, ulceration, scars, and perforation.

2. In the cystic duct, impaction, ulceration, hyperplasia and surrounding infection.

3. In the common duct, ulceration and infection following lymphatics—chronic pancreatis—changes in the liver. There may be intermittent fever, termed by Charcot "intermittent hepatic fever."

BILIARY FISTULÆ

These may be internal or external. Internal fistulæ may join up with the stomach, duodenum, intestines, kidney, and bladder, and even with the bronchi, it has been said.

The diagnosis of cholelithiasis may be easy or difficult, or at times impossible. It is well to give a diagnosis of gallbladder disease and add, with probable gallstones. The x ray is of great diagnostic aid. Different workers report positive findings in stones in from twenty-five to seventy-five per cent. of cases. However, a negative reading does not exclude the presence of stones.

PROGNOSIS

It is plainly evident that in a given case of gallbladder disease, subject to so many changes and factors, our prognosis depends upon the extent of pathological or morbid changes, the extent and duration of infection, the condition of the biliary tract, the type of infection and the clinical types of gallbladder disease. This, combined with the general resistance of the patient, gives us our outlook on prognosis. In a general way the better our interpretation and judgment of clinical and pathological findings in the patient, the better will be the end result or prognosis. In the acute suppurative cholecystitis, with extending infection and peritonitis, the prognosis is necessarily grave, while in the acute nonsuppurative, catarrhal cholecystitis, with or without calculi, the prognosis is good. In a chronically infected gallbladder, with or without calculi, the ultimate outcome depends, aside from the skill of the surgeon, upon the methods of surgical treatment. As a general rule, the removal of the gallbladder

(cholecystectomy) offers a much less subsequent morbidity, but carries with it a slightly higher mortality.

CONCLUSION

In general, the viewpoints of Moore and Mayo reflect the best available opinions of the best surgical minds in preferring cholecystectomy to drainage. It is worthy of note that opposite opinions are most generally held by men of more limited experience, or those early in their surgical careers. It does not seem justifiable to make use of the results of such limited experience in making correct judgment as to the type of operation to be performed in gallbladder disease. It seems more proper to make use of the experience of men advanced in surgical knowledge and practice, and when all the published reports obtained under the latter conditions show a marked uniformity in preferring cholecystectomy to drainage, as a routine operation, it seems idle to speak of the unsettled opinion in regard to the proper operation for gallbladder disease.

5 East Garfield Boulevard.

Case Illustrating That an X Ray Study of the Gastroenteric Tract Is Not Infallible*

M. GOLOB, M.D.
New York

The x ray study of the *prima via* undoubtedly conveys such a vivid impression of the truly scientific investigation as to lead quite naturally in the conclusion that its findings are infallible. Hence it is not surprising, though a matter of regret, that many physicians have come to regard it as the short cut to a certain diagnosis. Even to the lay mind, the röntgen study makes its appeal as the only method of establishing the existence of basic pathology.

Some of our best röntgenologists have taken note of the wide prevalence of this belief in the x ray's infallibility and have warned us of its fallacy. Stewart states that "the usual röntgenograms, before and after defecation, following the colon with an opaque medium, are not sufficient in many cases to reveal the lesions." (1)

Carman reports two contrasting cases: 1. Adenocarcinoma of the stomach revealed by röntgenogram but not palpable on exploration by the surgeon. 2. A gastric ulcer not shown by the röntgen ray but found at operation. He says: "One demonstrates the difficulty experienced sometimes by the surgeon in locating a lesion after it has been revealed by the röntgen ray, and one demonstrates that the röntgen ray is not infallible in the diagnosis of gastric ulcer." (2)

The case I wish to present demonstrates that, while a röntgen investigation aids us in diagnosis when the findings are positive, it often presents findings that are negative, and therein constitutes a danger to the extent such findings halt further inquiry.

Case I.—The patient was a male, twenty-nine years old, a barber by occupation. His family history and previous personal history, except for dysentery and gonorrhea, were negative. His present illness was of short duration, i. e., six months. His chief complaints were pain in the lower abdomen after meals, intermittent vomiting for about four days, no hematemesis, and diarrhea lasting for about three weeks. At the time of the examination, his appetite was good and bowels regular. He had lost ten pounds during his illness. There were no symptoms referable to the genitourinary tract.

The patient was of the asthenic habitus. Abdominal examination revealed tenderness in the upper left quadrant on deep palpation. A small mass was felt in that region which moved with respiration. Liver and spleen were not palpable. Neurologically he was found to be negative. Blood showed secondary anemia. Gastric analysis of an Ewald test meal showed an entire absence of free hydrochloric acid, and a total acidity of 12. The bladder was catheterized, cystoscoped, and the ureters catheterized, but no gross pathology noted. The urinary flow from both kidneys was slow; that from the left being slower and the urine lighter in color. The pyelogram revealed a sharp extrapelvic angulation in the left ureter. The report expressed uncertainty as to whether this resulted from an intrinsic or extrinsic tumor of the kidney.

Radiography of the gastroenteric tract revealed no pathology. A barium suspension enema disclosed no lesion in the colon. An additional fluoroscopic investigation with a barium enema showed the colon filling perfectly and it was easily discernible that the palpable abdominal mass was separate and distinct from the colon below the splenic flexure.

The diagnoses tentatively made were: Dislocated spleen, floating kidney, hypernephroma.

The following is a report from the Roosevelt Hospital: "An exploratory colostomy was performed on January 12, 1925. An upper left rectus incision was made. The terminal transverse colon, splenic flexure and the whole of the descending colon were involved in a massive carcinomatous growth, firmly fixed with metastasis into the small intestine. The condition was inoperable."

Notwithstanding the sharp criticism that is usually bestowed upon exploratory surgery, this procedure was evidently justified in this case, for not until the "curtain of the anterior abdominal wall was withdrawn" was the correct diagnosis made.

Carman is right in saying that "thorough reliance on the röntgen ray is a gratifying compliment, but it sometimes leads to error."

Instruments, Apparatus, and Clinical Notes

A NEW RECTOSIGMODOSCOPE*

J. F. MONTAGUE, M.D.
New York

In offering to the medical profession a rectosigmoidoscope of novel design an effort has been made to furnish an instrument which would be easy to introduce, give but little discomfort to the patient and at the same time furnish a superior view of the rectum and sigmoid colon.

Obvious and admitted deficiencies in current types of proctosigmoidoscopes are eliminated and many new features introduced. The instrument consists of three parts: a barrel (B) either fifteen or twenty-five centimetres in length, three quarters of an inch in diameter, calibrated in centimetres, and furnished with a nonrolling flange (F) at its proximal end. Second, an obturator point (O) which fits on to an inner tube. Both of the above parts are durably made and may be sterilized by boiling. Third, the inner tube (I) which slides like a telescope into the barrel of the sigmoidoscope. It acts as a light (L) carrier and has an attachment for the obturator point. The interior of this inner tube is of a dull black gunmetal finish which successfully obviates reflections throughout the barrel of the sigmoidoscope. This inner tube acts as a combined dark chamber light carrier and by means of the obturator point combined also as an obturator. The distal part of this inner tube is exposed sufficiently to enable thorough cleaning. The proximal end of the inner tube is provided with a swinging window (W) which cannot be lost but which may be swung open to permit topical applications or instrumentation through the scope. It is also provided with a binding post for electrical (E) connection and an inflation nipple (A) for bulb attachment.

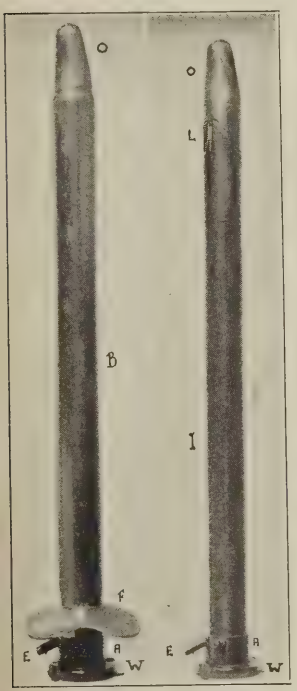

Fig. 1 Fig. 2

FIG. 1.—Rectosigmoidoscope ready for use.

FIG. 2.—Inner tube of scope with obturator point in place.

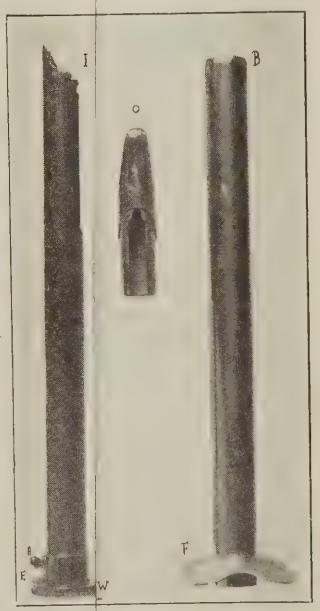

FIG. 3.—Showing the three parts of the scope; inner tube, obturator point and barrel.

The manner of using this instrument is as follows: After inflating the instrument with air the obturator point is gently inserted into the anal canal. Its dilating point gently divulses the sphincter without discomfort to the patient. Through perforations in the obturator point air passes into the bowel and by gently inflating it dilates it in advance of the instrument. When the instrument has been passed the requisite length the inner tube is withdrawn leaving the scope *in situ*. A simple slight pressure releases the obturator point which may be dropped into a sterilizer. The inner tube is then lighted and reinserted. During insertion of the inner tube it may be seen whether the field is clear and should there be any liquid feces they may be dealt with, without soiling the lamp, by merely withdrawing the inner tube to a safe distance. Then through the swinging window the area may be sponged clean and the inner tube advanced. Now by withdrawal of the entire scope all the mucosa of the sigmoid colon, rectum and anal canal may be completely and easily examined.

For the sake of brevity, and at the risk of bluntness, the features of this instrument which I believe render it attractive may be stated as follows:

1. The instrument is compact, easily sterilized and durable. It may be carried in any doctor's bag of ordinary size without the need of a special case.

2. The dilating point facilitates easy insertion by gradually dilating the sphincter during its introduction.

3. The pneumatic obturator dilates the bowel in advance of the instrument by gentle inflation.

4. There is a dur-

*Read before the New York Academy of Medicine, Section on Surgery, April 3, 1925.

able distal light which may be withdrawn should there be danger of liquid feces soiling it and which affords light during the entire retreat.

5. The diameter is that which experience has shown to be most acceptable to the average patient.

6. There are no reflections in the barrel of the scope owing to the darkened interior.

7. The instrument is simplicity itself. There is no cumbersome handle nor awkward obturator.

8. It may be used either on a battery such as that used for otoscopes or may be used with house current provided a rheostat is used.

9. Those parts of the instrument which touch the patient can be readily sterilized by boiling. These parts are strongl made, the delicate part of the instrument, that is the inner tube which carries the light and electric viring, may be easily cleaned without damage.

The instrumen should find use in rectosigmoidoscopic examinatin, in the topical applications of medicines to the olon or rectum; for the obtainance of biopsy specimns; for the cauterization, fulguration or removal c polyps in the rectum or colon. It may also be usec for other operative procedures in the rectum and clon for the implantation of radium in malignant' grcvths and for many operative procedures on the lo/er bowel.

Physiological Transfusion Appiratus

HARRY KOSTER, M.D., F.A.C.S.,
Brooklyn, N. Y.

Before presenting a new apparatus for transfusing blood it would perhaps be advisable to briefly mention the desiderata for ideally accomplishing the operation. Then, a comparison of the newly devised method to the ideal will be productive of the most severe criticism possible and also of true evaluation.

The ideal method of transfusing blood would be to convey it directly from the bloodvessels of the donor to those of the recipient through a channel lined with vascular endothelium without interruption of continuity at the points of contact. The nearest possible approach to this ideal is represented by direct suture of the artery of the donor to the vein of the patient, or by coaptation of the donor's and patient's vessels by means of a Crile cannula or some of its modifications.

The difficulties of technic, the surgical experience and the time necessary for the performance of this operation have all combined to make it an impractical method for the large number of physicians who are called upon to do transfusions.

The semidirect method is a step removed from the preceding, in that some form of tube or cannula is used to bridge the gap between vascular systems. The tube is made of glass or silver, one end is tied into the donor's artery and the other into the recipient's vein, the tube having been previously paraffined to diminish the tendency towards coagulation. This method has none of the difficulties of the previously described one, but the dose cannot be measured accurately, and there is danger of a cardiac dilatation in the recipient because of the marked increase of pressure to the right auricle brought by the high pressure from the artery of the donor.

The indiect methods which have dominated the field of recent years are: 1. The paraffined tube, of Kimpton and Brown, Percy, David and Curtis. 2. Needle and syringe apparatus of Lindeman and Crotti. 3. The valve and syringe method of Miller and Unger. 4. Addition of anticoagulants as the citrate of Weil and Lewisohn or herudin of Satterlee and Hooker. 5. Using defibrinated blood.

The tube method necessitates dependence upon a paraffin surface s an anticoagulant, which is not always reliable. 'hen the blood remains in the tube for a considerabl period of time before being injected into the reipient. In this connection, Novy's work is interestin. He found that ten c.c. of blood drawn from a rabit and immediately injected into a guineapig causd Little or no reaction, but that if the blood were kot in the syringe for three minutes before being injeted it became toxic, two c.c. becoming a lethal dse. This furnishes another objection to the paraffied tube method.

The needle andsyringe method of Lindeman and others is satisfacory in their hands because they have developed acorps of well trained assistants, which is indispensble for the rapid transference and cleansing of the seies of syringes, but for that reason has not received vider application.

The valve and syringe methods of either Miller or Unger are alsc satisfactory when used by them. The technic necesary for the avoidance of a fiasco is rigid and allowsof no variation or deviation, and since it involves sveral varieties of movements, an error frequently ocurs and vitiates the result. For instance, the barr sticks in the syringe and saline must be used to wsh it out and cleanse the connections. Or, duringthe passage of saline through the apparatus the opertor becomes confused and begins to draw back the lood from the recipient.

When successfily performed, a transfusion by either of these methods gives a minimum reaction.

The anticoagulat method received wide application during the Wcld War and is perhaps the easiest method. The obections against its use are, the more or less severe reactions noted which result probably from a, ie introduction of the anticoagulant into the blood b, the agitation and standing of the blood which cuses destruction of some of the blood elements an production of toxic substances.

The use of defibinated blood, of course, has many objections such as marked reaction, removal of important constituent rendering it less potent in restoring the hemoglobin content of the recipient.

A new method herein described is believed to

present so many advantages that it will probably supersede all others because of its universal applicability. The apparatus is accompanied by an adjustable base which can be clamped to a board upon which the arm of the recipient and that of the donor rests, so that the apparatus can then be mounted be-

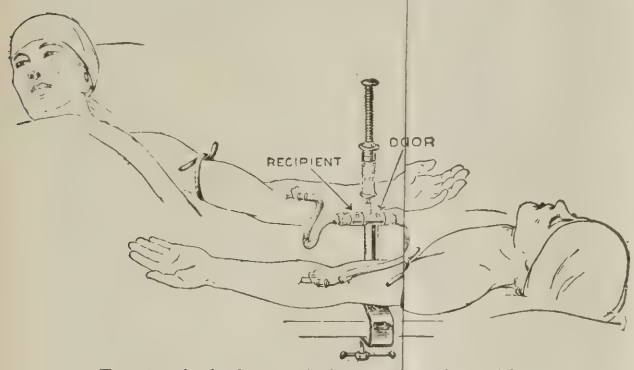

FIG. 1.—Author's transfusion apparatus in position.

tween the two elbows. It consists of a donor's end, a recipient's end, and an outlet between the two, to which a two c.c. record syringe is connected in an upright position. Between the ends and the syringe outlet are two ball valves so arranged that pressure on the syringe opens one and closes the other, and aspiration action of the syringe closes the first and opens the second. The valve action is made foolproof by the use of fine springs which ensure perfect closure. The bundle of the syringe plunger is fitted with a tension spring which automatically withdraws the piston from the barrel and thus automatically aspirates. The upright position of the syringe allows easy emptying by a downward thrust from the palm of the hand on the handle of the syringe plunger. Release of the hand is automatically followed by aspiration of the syringe plunger because the tension spring immediately withdraws the piston. Fig. 2.

The donor's and recipient's ends are stamped. Rubber tubing connection to the ends is made, needles are attached to the free ends of the tubing, the entire system is filled with warm saline by placing the donor's end in a saline solution and making a few downward thrusts on the syringe plunger until the saline flows out of the recipient's end. The needles are then inserted into the proper veins, i.e., donor's end into vein of donor and recipient's end into vein of recipient, and the syringe is emptied as rapidly as it fills by a downward thrust of the palm on the handle. Each thrust represents two c.c. and the number is noted until the total required is reached. The needles are then withdrawn and the operation completed.

The apparatus herein described has these qualities to commend it:

1. It offers a simple method for conveying measured amounts of blood from one individual to another under conditions of pressure and velocity which may be regulated by the operator.

2. The blood is in contact with a foreign surface for considerably less time than in any other method.

3. The operator is never hindered by sticking of the piston in the barrel. (A serious objection in other syringe methods.)

4. With this method, therefore, merely one syringe is necessary, a duplicate being provided only because of the ever present contingency of accidental breakage.

5. There being no stickiness or coagulation, a third valve to allow washing through with saline is entirely unnecessary.

6. After the apparatus is connected to the donor and recipient the repetition of only one movement is necessary to perform the entire transfusion. This eliminates an important vitiating factor, it being axiomatic that the greater the variety of movements necessary to produce a given result, the greater the possibility of serious error.

7. It automatically makes it impossible to reverse the direction of the flow and send blood from the prospective recipient to the prospective donor.

Let us consider these qualities in detail.

1. The only difficulty in performing the operation is in effecting satisfactory entrance to the veins of the donor and recipient. This is universal no matter what transfusion method is employed. The blood is measured by a calibrated syringe, the syringe itself is never moved. The piston alone is moved back and forth. The filling movement of the piston is automatically accomplished by the spring. The only movement necessary on the part of the operator is the push on the piston handle to empty the

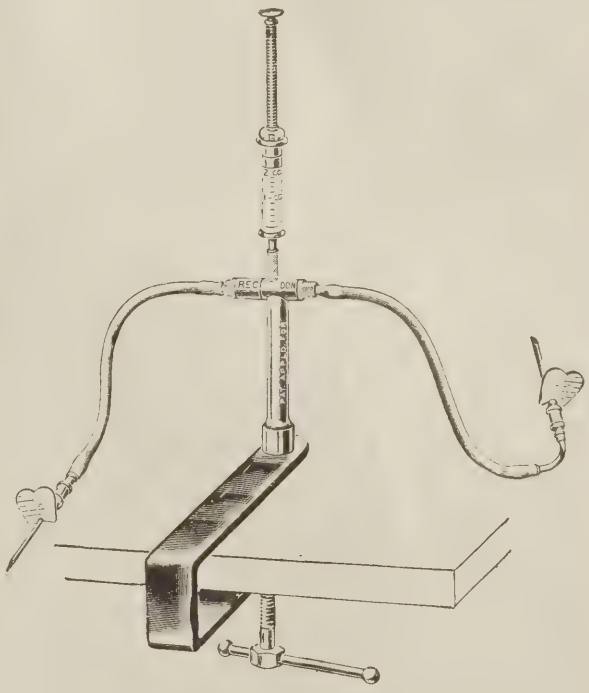

FIG. 2.—Author's transfusion apparatus

syringe. Thus the volume, velocity and pressure are easily controlled.

A two c.c. syringe is used. This offers a smaller surface for contact than a larger syringe. It can be filled and emptied in one tenth the time necessary to fill and empty a twenty c.c. syringe. The apparatus fits in between the elbows of donor and recipient so that a minimum of rubber tubing is necessary to

effect continuity between their respective veins. Thus the time that a drop of blood is in a container not lined by intima is considerably less than in any other method. The importance of this fact can not be too strongly stressed. Every indication points towards foreign contact as second in importance only to imperfect matching, in the etiology of transfusion reactions. It is to this that we attribute the absence of reactions in our cases. In not one was there any evidence of reaction as indicated by a chill or a rise in temperature.

3. The time necessary to fill and empty a two c.c. syringe, as stated, is fractional as compared to a similar procedure with a larger syringe. The actual time is less than the minimum time necessary to get breakdown of corpuscular elements to form tissue extract in sufficient quantity to cause stickiness of the piston in the barrel. This obviates a serious objection encountered in the use of other valve and syringe methods where it would be impossible, practically, to use less than a ten c.c. capacity syringe. Since no other apparatus has the automatic valve, with any other than the method herein described, each syringe manipulation would necessitate an accompanying valve regulation. Thus it would be necessary manually to open the donor's end, fill the syringe, close the donor's end, open the recipient's end, empty the syringe. This would constitute one set of movements. If a twenty c.c. syringe is used twenty-five such sets of movements would be necessary to transfuse five hundred c.c., but if one should attempt to use a two c.c. syringe, two hundred and fifty such movements would be required for the same amount of blood transfer. This manifestly would be impractical. Therefore, the attempt to prevent the objectionable stickiness (really an early coagulation phenomenon) encountered in other valve-syringe methods, by adopting the use of a two c.c. syringe, is impossible.

4. It follows then, since there is no stickiness of the piston in the barrel, that only one syringe is necessary, a duplicate being provided only because of the ever present contingency of accidental breakage.

5. The facts related in the two immediately preceding paragraphs are evidence of the superfluousness of a third valve to allow washing through with saline.

6. Shunting the blood from the donor into the syringe and from the syringe into the recipient is automatically accomplished. The negative pressure caused by withdrawing the piston from the barrel opens the valve on the donor side of the apparatus and simultaneously shuts the valve on the recipient side. Positive pressure, by plunging the piston onto the barrel, does the reverse, namely, closes the valve on the donor side and opens the valve on the recipient side. Thus, after the apparatus is connected to the donor and recipient by rubber tubing bridging the gap between the needles in the veins of the two principals, the only movement is the filling and emptying movement of the piston. Since the filling movement is automatically accomplished by the spring on the piston handle, the only movement necessary on the part of the operator is a downward thrust on the piston handle to empty the syringe. Thus th procedure is made as fool proof as possible.

7. The valves are opened and shut by definite differences in presure. The apparatus is so constructed that whe the syringe is full, if the recipient's end be closed off by clamping, it is impossible to empty thesyringe through the donor's end, because the greater the pressure exerted on the syringe piston the more tightly does the valve in the donor's end close.

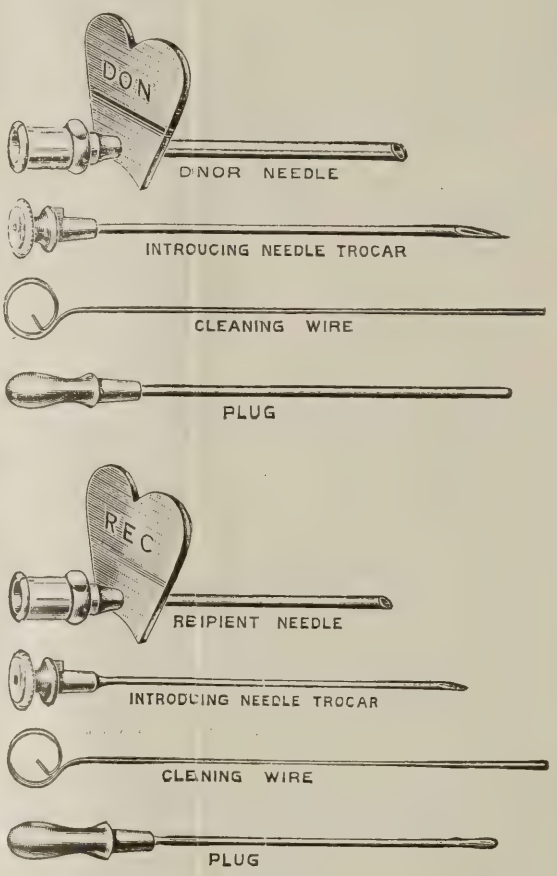

Fig. 3.—Parts of the author's transfusion apparatus.

If the donor's end be clamped and the piston withdrawn from is barrel no blood will flow into the syringe from the recipient's end because the greater the negative pressure in the syringe the more tightly does the valve on the recipient's end close.

Thus it is imposible accidentally to reverse the direction of the sream and send blood from the prospective recipiet to the prospective donor.

The apparatus i mounted on an adjustable base which makes it posible to fix it in such a position between the elbow of the donor and the recipient which will necessitte the use of a minimum of rubber tubing. This firther diminishes the foreign surface area and the length of contact time between blood and this surface.

By this method one thousand c.c. are transfused in less than eight minutes, no blood is lost, the operation becomes fool proof, reactions do not occur, and the operation of transfusion ceases to assume proportions of othe than a minor procedure. These statements are refrable only to the actual technic

of conveying blood from one individual to another and are based upon the premise that careful typing and matching of the bloods are routinely done.

It can readily be seen that the apparatus is adaptable to other uses. Infiltration anesthesia, aspiration of cavities, autotransfusion in ruptured ectopic cases are some of the procedures that may be accomplished with it.

By dipping the rubber tubing from the donor's end into the novocain solution, and attaching a needle to the tubing on the recipient's end, the apparatus is ready for use as a means for rapidly infiltrating a large area. It is only necessary to push the syringe plunger and guide the needle and anesthesia is rapidly effected.

After thrusting the needle attached to the donor's end into a pleural cavity containing fluid, the fluid can rapidly be withdrawn by pushing the syringe plunger.

In ruptured ectopic cases autotransfusion can be accomplished by connecting the recipient end of the apparatus to a vein and after connecting a glass funnel (covered at the wide end with two thicknesses of gauze for straining purposes) to the donor's end, placing the funnel in the pelvis and pushing the syringe plunger.

In summing up, the apparatus herein described is offered as an ideal medium for transporting blood from one body to another, because it most closely approaches all the conditions necessary for making blood transfusion universally a simple and safe procedure.

284 New York Avenue.

Intestinal Toxemia with Especial Reference to the Use of Colonic Irrigations.—Russell S. Boles (*Medical Clinics of North America,* November, 1924) states that clinical experience, together with a study of the literature, makes it evident that the condition known as intestinal toxemia actually exists, even though the toxins have not been demonstrated in the blood. Intestinal stasis initiates chemical changes and bacterial decomposition in the intestinal contents, and these forces working together produce alterations in the tissues that permit the toxins generated in the intestinal tract and bacteria to invade the tissues, bloodvessels, and lymphatics, and eventually to interfere with general nutrition and to bring about degenerative changes in the liver, pancreas, and other organs.

The symptoms of intestinal toxemia are manifold. They may be gastrointestinal, ocular, cutaneous, nervous or mental. A diagnosis of intestinal toxemia should be made only after careful physical examination and laboratory tests exclude the possibility of organic disease. The urine and feces should be submitted to careful chemical and bacteriological tests.

The aid of the x rays should also be invoked. The presence of an excessive amount of indican in the urine is a help in establishing the diagnosis; the best single index as to the degree of intestinal putrefaction is afforded by the determination of the ethereal sulphates. This procedure, however, does not determine the character of the putrefactive products.

Treatment must be directed to overcoming intestinal stasis, alleviating catarrhal processes, and restoring muscular tone. The character of the diet is of first importance and depends upon the type of toxemia present. In the indolic type, which is the most frequent, a low protein and high carbohydrate diet is indicated, while in the fermentative type the reverse is required. Much may be expected from the proper use of vaccines (particularly autogenous vaccines) and acid producing bacteria, such as Bacillus acidophilus. The latter should always be administered in milk cultures not in tablet form, combined with lactose.

Colonic irrigation is a valuable adjuvant in relieving stasis and atony and their resulting symptoms. Other aids in the treatment are the administration of agaragar and mineral oil, correction of faulty posture by well adjusted corsets or belts, outdoor exercise, special exercise and massage of the abdominal muscles, and deep breathing. The application of the faradic current following irrigation appears to be of value in overcoming atonic constipation. The use of laxatives is contraindicated.

Postoperative Pulmonary Embolism.—P. Lockhart-Mummery (*British Medical Journal,* November 8, 1924) states that at present there is no known means of ascertaining when a thrombus has formed in the great veins, and much less is there any means of treating it. The reduction of the coagulability of the blood of the patient before operation would be liable to result in equally serious disasters of another kind. The Trendelenburg operation, which endeavors to remove the thrombus from the pulmonary artery, has been done, but it does not seem sound, as patients who have survived a pulmonary embolism long enough to undergo an operation will probably recover anyway. It is to prevention rather than cure that we must look if we want to get rid of the mortality after operations from pulmonary embolism.

The present methods of anesthesia, which include a preliminary injection of morphine, probably tend to encourage thrombosis by slowing the blood stream during the dangerous period. The best method of preventing patients from getting postoperative thrombosis does not consist in altering the technic of operations, but rather in altering the methods of preparation and of aftertreatment. Preliminary purgation of the patient should be entirely abolished; if necessary it should be carried out five or six days before operation. The practice of starving the patient both before and after operation should be discontinued. The supply of proper mattresses on the tops of operating tables, and the prevention of the patient assuming a constrained position during the operation which would cause pressure upon the veins, are points requiring greater attention. The frequency of embolism after gynecological and gallbladder operations is possibly attributable to the unnatural positions in which the patients are placed. The author thinks that we should attach more importance to the comfort of the patient on the operating table than we do at present. The patient being unconscious, we allow him to remain for an hour or more in a most constrained position, which will embarrass the circulation in the lower limbs and pelvic veins.

Editorial Articles

EXHAUSTED NUTRITIVES

We, or at least our children, are urged these days to eat various things which we do not want, and might, therefore, on general principles, seem not to need. Bowing to authority, many of us have followed humbly the leadings of the "nutrition workers" and have taken spinach and carrots and their ilk as a matter of conscience. William James preached that it was good for us to do something disagreeable every day, so aside from the iron and lime and those elusive vitamines which we are supposed to get, doubtless we have received much material for moral upbuilding.

We make no complaint against this diet (even if we do not like it) provided we really take in the ingredients which are supposed to be contained in the prescribed foods.

Now cometh the agricultural scientist and deposeth that spinach is, in many a garden patch, suffering from chlorosis. If the spinach suffers from chlorosis, will not the human who depends on spinach for his daily supply of iron also suffer from chlorosis? In the Rhode Island Experiment Station they have found that the application of manganese sulphate to the soil cures the condition. Why not apply the manganese directly to the human plant and secure immediate results as to the supply of iron?

Milk is recommended as a sure source of vitamines and minerals. Are we certain that these are present in the milk we happen to purchase? They may be all there, but it is known that their quantity varies according to the food of the cow, and, in the efforts to secure a maximum of lacteal fluid, the proportion of food materials in the milk is anything but that of the cow on her natural pasturage. It looks as if we might come to a time when we would need to prescribe for the child not merely milk which we know to be comparatively free from bacteria and containing relatively right amounts of proteids, sugar and fat, but also milk that fills the specification that there be sufficient representation of the accessory food materials and of minerals. We are all quite aware that there has been adulteration of certain foods and that important elements have been refined out of some of our common foodstuffs, notably flour, but that, for commercial ends, these have been reduced in milk needs also to be kept in mind.

The nutritionists have been shaking down their knowledge of late and are becoming less restrictive in some of their teachings. In fact, they are becoming so liberal as to say that, so far as mere feeding is concerned, if we will restrict our intake of sugar we will be fairly in a way to live long and prosper. This sounds sensible, for sugar (in the amounts available) is man's unnatural food which has such an immense attraction for him that he cannot (by inclination) do other than consume quantities not good for him and, in so doing, overcharge his blood stream with this substance to its impoverishment in other substances needed for the best conditioning of all tissue.

THE TOLL OF THE STREETS

Progress is not always an unmixed blessing. For example, progress in locomotion and transport has not been so. Statistics of the deaths and injuries brought about by automobiles and motor traffic generally can be fitly characterized only by the word appalling. With monotonous regularity announcements are made in the daily journals that so and so was killed in an automobile accident or was knocked down and seriously injured while attempting to cross the street and sometimes an accident on a large scale takes place in which several people are the victims of careless driving or of untoward circumstances.

The inhabitants of this country seem to have become inured, to a large extent, to this kind of thing and to regard it as an occurrence which must be looked for as a customary happening. When subjected to calm consideration, the toll of the streets and roads due to automobiles appears in its true light as a blot on civilization. While the automobile and its kin exact a heavy toll of life and limb in all the countries of the world, America easily occupies the first position in this respect. True, motor traffic abounds in this country more than in any other, but even when this is taken into consideration, in proportion to the number of motor driven vehicles and to population, accidents here are more common by far and, as a rule, more serious than in European countries. It is said that 22,000 deaths and 675,000 serious accidents in this country were one result of automobile driving during 1924; fifteen per cent. of the casualties being children under the age of sixteen.

There appears to be an especial lust for speed on this side of the Atlantic and too rapid automobile driving seems to have become a national obsession. There is also another indictment which may be urged against the abuse of the automobile and that is its bad effect on the nervous system. The coming of motor transport was coincident with the high tension of modern modes of living, and really the advent of the automobile and its development appears to have been a factor largely responsible for the stress and strain

of modern existence. The high speed automobile has made and makes for high speed life, and this kind of life renders the individual restless and nervous, his blood pressure rises, and eventually his originally strong constitution breaks up suddenly and he dies in what should have been the prime of life from cerebral hemorrhage or heart failure.

A class of the community which suffers grievously from the abuse of the automobile is the pedestrian. Even in this country, in which almost every one owns an automobile, there are still a goodly number of persons who are pedestrians by choice or through lack of means. Such persons suffer both in nerves and limbs from the ubiquitous automobile or the rushing motor cycle. Crossing the streets is not only often dangerous but nerve racking and, moreover, the traveler on foot is not always treated with the consideration that is his due. The automobile has taken its place as the popular means of transit of the American people, and the lust for speed is gratified as far as is possible. There are some streets in some cities in which the traffic is so regulated that comparative safety is ensured the walker in crossing. But in many streets in many cities crossing is attended with risk and tries the nervous system somewhat severely.

The perils of the pedestrian are many and obvious in any American city and this remark applies with equal force, to a lesser extent, to the country, where although traffic is of course less, regulations are more frequently evaded, and there are opportunities for accidents, such as steep declines, sharp turns, and, above all, level crossings which very rarely exist in the towns. However, the danger of accidents in the country does not greatly concern the pedestrian, but mostly the drivers and occupants of motor driven vehicles, as the walker generally avoids, as he would avoid the plague, country roads favored by motorists.

There is no intention in this editorial to write a diatribe against automobiles or motor traffic generally; that would be indeed "kicking against the pricks," but the intention is to inveigh against the abuse of a means of locomotion and transport which has revolutionized our views of traveling by road and to point out that it is incumbent on the authorities to protect the nonmotoring public against the drivers of motors and the motorists against themselves. The list of deaths and injuries due to this cause is too great to pass over as a part of the price to be paid for progress, especially when it is a matter of common knowledge that in cities a fair proportion of fatalities and injuries are preventable. On the whole, the regulation for the protection of the public at large in big cities is well conceived and efficiently carried out. A large number of accidents are owing to the carelessness of foot passengers and to the carelessness and ignorance of drivers. The fact also must be borne in mind that "material progress in all that concerns movement has been so rapid that it has outstripped man's rate of adaptation." Neither our roads nor our streets nor our nervous systems are adapted for the automobile. Most of our city, town and country streets or roads, and this is the case in Europe more than here, were built in an era when men not only knew not of the automobile but did not dream of it. Roads and streets are therefore too often narrow and winding.

The true remedy for the existing state of affairs is to construct everywhere, both in town and in the country, streets and roads fully adapted to the use of the automobile. This, while expensive, seems to be the only effective way of securing safety, or at least comparative safety, for the public and the motorist alike. In the meantime, strict protective regulations should be enforced in every city and town and in every street of city and town. The toll of the streets calls for prompt action.

MEDICINE AND DENTISTRY

Italy was, at one time, the world's centre of medical training. William Harvey sat at the feet of an Italian professor before entering upon his career.

Italy seems again at the front in making it, by royal decree, obligatory that all dentists must be profesionally qualified in medicine and surgery and that every medical graduate must also acquire a considerable knowledge of dentistry. At last the teeth are to be recognized, at least in Italy, as a part of the human organism as much as the eye or the ear, and not as so many stones which Nature threw into our mouths for good measure and which have no physiological connection with the other bodily structures.

We are moving, or at least making a gesture, in this direction in this country in combining (as has been done at Harvard) medical and dental education under one supervision. The Italians are far ahead of us, however.

In this connection it is interesting to note that in another foreign land, the province of Natal, South Africa, advance regulations in regard to professional conduct of dentists have been set up which should make us sit up and think. "Any dentist entitled to practise in Natal who shall publicly exhibit specimens, appliances or apparatus of a dental or other nature; or advertise either in the newspapers, or magazines, or by handbills or stationery, billheads, telephone or other directories, or by any other similar agency; or attempt to attract patients by means of advertisements published in newspapers, or circulars.

or by handbills, describing methods of practice, patented or secret processes, or of such nature as to indicate claims of superiority over other practitioners, or depreciating the value of their work; or publish or allow to be published, or exhibit or allow to be exhibited in any place whatsoever, his scale of professional charges, whether fees alone are mentioned, or cheapness or other advantages; or display or allow to be displayed, his name or occupation or both in any window or signboard or use any advertising sign other than the usual nameplate recognized by the medical profession; or practise in any other name than his own; or fail to comply with any notice issued by the council regarding advertising in breach of this regulation; shall render himself liable to be adjudged by the Medical Council to be guilty of disgraceful conduct in a professional respect, and to have his name erased from the register."

If we had regulations in this country which would do no more than remove the display of artificial teeth from our main streets, they would be a decided advance towards a civilized community.

We may learn much from Italy and from Natal.

THE PRACTITIONER AND THE VENEREAL DISEASE CAMPAIGN

During the days of the war when the necessity for conserving the manpower of the nation was uppermost in everybody's mind, the venereal disease problem occupied the minds of a great many persons in the medical profession and the lay public. It is trite to say that the need for warfare against the venereal diseases did not cease with the Armistice; that the necessity for the conservation of the nation's man power is just as real in peace as in war. Yet unfortunately there are a good many people in the medical profession who do not realize this, or if they do are not willing to give heed to it.

Great headway has been made by the Public Health Service in the reduction of morbidity rates of the venereal diseases and the medical profession has played a considerable rôle in the production of this result. But the indications are that the medical profession is not as of old taking as active an interest in this matter as it should. The appropriations which the federal government has made for the conduct of this work have been gradually cut and in the carrying out of the economy program there is grave danger that this very necessary and useful activity will be starved to death.

The federal government began the antivenereal disease work for the nation. It has not yet completed the job in this regard. The States still need assistance, aid and advice in carrying out their legislative, curative, educational and eradicative measures. The dignity and influence of the federal government is necessary in order that the program for the various States may be uniform; that their educational work shall be along certain well worked out lines; and in order that advantage may be promptly taken of the discoveries made by research. This is no time for the practitioner of medicine to lose interest in this matter. It is one which concerns him and his family as well as the entire community, and the necessity for the conservation of the public monies is not such as to require the federal government to withdraw its forces from the battle against the venereal diseases.

HEART DISEASE AND RHEUMATISM

Heart disease has increased in civilized countries and is now among the first three most deadly maladies known. Indeed in Great Britain in 1923 heart disease in various forms stood at the head of the list of mortal diseases. However, as the socalled rheumatic diseases are prevalent in that country and as certain rheumatic diseases are notoriously the precursors of heart diseases this is not to be wondered at. But, as said before, heart disease is quite common in all civilized countries and therefore as some forms of rheumatism are known to bring about heart disease, the rational treatment is to prevent cardiac complications by preventing rheumatism.

A valuable report on The Incidence of Rheumatic Diseases has emanated recently from the British Ministry of Health. This report is peculiarly valuable because it deals with the observations of general practitioners who are also insurance practitioners, commonly known as panel doctors, which have been prepared by a committee of the medical staff of the Ministry of Health. It consequently covers a wide range as it is the general practitioner who sees diseases in their early stages, and represents a combined effort including a team inquiry of general practitioners. In no case is the cause of rheumatism known and it is hard to stimulate public interest in a disease of unknown origin.

The report throws out two suggestions which of course have been suggested frequently previously. Portals of entry are of importance, the tonsils being under grave suspicion. According to the report "fifty per cent. of the patients with acute rheumatism had enlarged or septic tonsils, and only two per cent. of patients with acute rheumatism had a history of having their tonsils removed." Again, dental sepsis has for long been suspected as providing foci for spreading toxins and provoking an attack of rheumatism. There is no intention to attempt to show that these septic conditions may be accounted as first causes; only the suggestion is made that fur-

ther research on the subject is required. Cause must not be confused with effect. It may be rheumatism predisposes to septic conditions and not septic conditions to rheumatism. This is an old battle ground of medicine and is a question that if elucidated would unravel the tangled skein considerably. In any event mouth, teeth and tonsillar defects should be treated effectively early and promptly, for whether they be causes or effects of rheumatism, their continued existence is prejudicial to the health of the patient.

With regard to the avoidance of heart disease then there is need in rheumatic people to prevent the onset of heart disease and with this end in view the report advises thus: "The concentration of acute rheumatic cases in a special hospital with cardiological and pathological departments, preferably situated in a country district, would probably be followed by a great advance in our knowledge of the disease and of the prevention of valvular disease of the heart." It seems that if heart disease is to be largely prevented that first the problem of rheumatism must be solved. It is believed by many that chronic rheumatism is due to a toxic cause and that these toxins originate in the gastrointestinal tract brought about by long continued intestinal stasis, which in turn is the result of errors of diet, lack of sufficient exercise, fresh air and so on. There may also be, as Llewellyn has suggested, a socalled rheumatic diathesis. At any rate, it appears to be reasonably certain that a great deal of heart disease will be avoided if rheumatism is prevented, and in order to effect this successfully the causes of rheumatism or of socalled rheumatism should be thoroughly probed. In the meantime certain clearly indicated precautionary steps should be taken, as careful and suitable diet, a sufficiency of fresh air and exercise and keeping the organs of excretion and elimination working freely and regularly.

IN THE CAUSE OF MEDICAL SCIENCE

The list of those who have sacrificed their lives to the cause of medical science is long and is being added to constantly. Since the discovery of the x ray and radium, the roll of martyrs of those who have employed it for the benefit of their fellowmen, is a formidable one. The latest victim is Professor Bergonie of Bordeaux, who has just died from the effects of radium burns. In the scant thirty years since 1895, when Röntgen announced his discovery, there have been no fewer than 140 such casualties among persistent workers in this branch of medical scientific treatment. Most of these have been more or less obscure toilers, such as young laboratory assistants, journeymen radiographers, and the like. Yet there are also some very illustrious names on this roll of honor.

Antoine Henri Becquerel, of the *Musee d'Histoire Naturelle* at Paris, distinguished as the discoverer in 1896 of the radioactivity of the metal uranium, is the earliest known sufferer. He carried a small tube of radium and burned his fingers severely. The lesions healed, however, and he was not injured permanently. The radium workers soon learned to protect themselves, and it has been the workers with the x rays who have been the ones unwittingly to lay up suffering for themselves in the years to come. It took the x ray workers several years to realize the dread significance of the socalled x ray warts. It is indeed from these earlier workers that the long list of killed and injured is mainly drawn.

Nowadays both radium and x ray are so protected that they are harmless to the operator and it is doubtful whether there are any cases of x ray or radium cancer today which do not date back ten years at least for their inception. The harmful potentialities of x ray and radium seem now to have been thoroughly explored and protected against. While the exploration has cost many lives, the experience gained has been valuable, and there is no doubt that these martyrs to medical science would be the first to acclaim this fact. Professor Bergonie and the others who have heroically laid down their lives in the cause of medical science and for the benefit of their fellow creatures have not made the sacrifice in vain. They have died as truly as any heroes of the battlefield, that others might live, and are more glorious as heroes of peace than of war. Moreover, as the result of their efforts both discoveries are thoroughly established as safe and healing agencies of the highest value.

INSURANCE WITHOUT MEDICAL EXAMINATION

Several months ago one of the largest and best known life insurance companies of the country made the surprising announcement that thereafter on business examined within two years, additional insurance up to $10,000 would be issued without medical examination. Another company had already set aside one month a year during which this privilege was available, and others conceded the writing of twenty year endowment policies up to $2,000 without medical examination, all showing a tendency toward unexamined business.

Protection is afforded by the fact that this privilege is open only to those who have been examined within two years. A written statement of health is required which is an additional safeguard. The object was, according to the company, to strike the average, not to segregate a highly superior group. British and Canadian companies have written unexamined business with great success. The Sun Life

Insurance Company has written this type of business since 1902, and has improved the status of the class until the cost of the insurance is the same to them as to those who have been examined.

The *National Underwriter* says in regard to the matter that "the success of group insurance in the amount of business being written without examination is advanced to show the practicability of insurance without examination. With an inspection report required and reliable agency force, there is no reason why an average group should not be obtained, is the opinion of those advancing the plan. A number of states require medical examination, and in these states of course the plan cannot be put into effect. . . . It can probably be predicted that, if this practice of writing insurance without examination becomes general, the law will eventually be repealed or waived in all the states."

SYPHILIS AS A CAUSATIVE FACTOR IN HEART DISEASE

In a recent report the Division of Venereal Diseases of the United States Public Health Service states that, if the figures for heart disease given in the latest census are correct, syphilis may be held responsible for fifty-two per cent. of all deaths resulting from heart trouble, amounting to 88,417 fatalities. The census figures referred to cover the registration area, which comprises 87.6 per cent. of the population of the country. They show that heart disease in 1923 was responsible for 170,033 deaths, as compared with 105,680 deaths caused by pneumonia and 90,732 by tuberculosis. Syphilis is credited with causing 15,811 deaths in the census, and if to this number we add the fifty-two per cent., or 88,417 fatalities, the result is a total of 104,228 deaths caused by syphilis, exclusive of deaths caused by some other diseases which are in many cases the result of syphilitic infection.

Experiments in Paris have apparently indicated that seventy-six per cent. of syphilitics suffer from heart disturbances. Autopsies on 155 persons known to be syphilitic showed 115 cases in which vascular lesions of the heart were present.

News Items.

Health Survey of Memphis.—Dr. Haven Emerson, of New York, is conducting a health and hospital survey of Memphis and Shelby county, Tennessee, on the invitation of the mayor of Memphis.

Change in Editors.—Dr. Frank A. Rector, formerly of the Conference Board of Physicians in Industry and the National Industrial Conference Board, is the new editor of the *Nation's Health*, succeeding Charles E. A. Winslow, Ph.D. of Yale University.

Theatrical Hospital Plans.—Dr. George O'Hanlon, general medical superintendent of Bellevue and Allied Hospitals, is to become vice-president of the new Theatrical Hospital of New York. The hospital will occupy what is known as the Ziegler Town House, at 2 East Sixty-third street, on the completion of alterations.

Graduate Work at Tulane.—The graduate school of medicine of Tulane University is to be reorganized to meet more fully the recommendations of the Council on Medical Education of the American Medical Association; it is expected that the reorganization will be completed for the coming college year.

British Medical Association Election.—The following officers were elected at the annual meeting of the British Medical Association: Robert George Hogarth, F.R.C.S., of Nottingham, England, president; Alexander Primrose, M.R.C.S., and Frederick N. Gisborne Starr, C.B.E., both of Toronto and C. P. Childe, F.R.C.S., vice-presidents.

Public Health Institute.—The Chicago Medical Society states that in its opinion the Public Health Institute of Chicago is an unethical institute in every sense of the word and that physicians connecting themselves with the institute will be brought before the ethical relations committee of the society. This institute specializes in genitourinary diseases, and uses full page advertising for publicity.

Health Statistics of Metropolitan.—The Statistical Bulletin of the Metropolitan Life Insurance Company, based on 16,000,000 industrial policy holders of this country and Canada, announces a death rate of 8.5 per thousand in 1924, a decrease of 5.2 per cent. from the year before, and states that 1924 is the first year in which every important cause of death showed a decrease from the previous year. Epidemic diseases of childhood showed the lowest rate on record. The diphtheria rate in particular shows a drop of fifty per cent. from ten years ago.

New Director of the Medical Publicity Bureau.—The Medical Publicity Bureau takes unusual pleasure in announcing the appointment of Dr. John James McNulty as its active director. Dr. McNulty, who is the son and grandson of a physician, began his career as house physician to the Presbyterian Hospital of New York. Dr. McNulty is one of the pioneer endocrinologists; his various researches and his experience in the practical aspects of medicine combine to make him an ideal director of the bureau.

Personal.—Dr. David W. Tovey has been appointed as professor of gynecology at the New York Postgraduate Medical School.

Dr. I. Seth Hirsch has returned to this country after attending the recent International Congress of Radiology, Physics and Physiotherapy at London.

Dr. Christopher J. Patterson has resigned as director of the Marshall Sanatorium of Troy, N. Y.; he will be succeeded by Dr. George S. Amsden, of Albany.

Dr. James L. Cochran of Connellsville, Pennsylvania, has been elected president of the Association of Baltimore & Ohio Railroad Surgeons.

Dr. Frederick W. Sears, health officer of the Syracuse district, New York, has been requested to give one of the DeLamar lectures at Johns Hopkins University.

Dr. Mont Reid, of the University of Cincinnati College of Medicine, has gone to China as professor of surgery at the Rockefeller Institute, Peking, China.

Dr. William W. Graves, of the St. Louis University School of Medicine, has been invited to deliver a lecture before the University of Edinburgh.

Hospital News.—The contract has been let for the construction of a new nurses' home at Johns Hopkins, to cost about $650,000, and accommodate two hundred and forty nurses. The Presbyterian Hospital of Philadelphia is conducting a campaign for $1,500,000.

Ground has been broken for the new building of the Mary Immaculate Hospital, at Jamaica, Long Island, to be built at a cost of $1,500,000.

A new municipal hospital will be built by the city of Rochester, adjacent to the new buildings of the university.

A campaign for $1,350,000 for Mount Sinai Hospital, Cleveland, has been started; the funds will be used for dispensary, laboratory, and nurses home.

Fordham Hospital, New York, is to enlarge its nurses' quarters, at a cost of $500,000 to accommodate 122 nurses.

The Board of Estimate of New York has authorized the purchase of Lincoln Hospital, in the Bronx, at a cost of $750,000. The hospital will be under the jurisdiction of the Department of Public Welfare.

The recent campaign of the Beekman Street Hospital, New York, yielded $354,000.

The Bloomingdale Hospital for Nervous and Mental Diseases, White Plains, New York, has received an anonymous gift of $100,000; this will be used as a building fund.

The cornerstone of the New York City Cancer Institute, at Welfare Island, has been laid. Experimental research laboratories will be contained in the building.

The Report of the Subcommittee on the Convalescent Care of Medical Patients of the Public Health Committee of the New York Academy of Medicine

The purpose of this inquiry is to examine into the needs of convalescent patients, to suggest the general principles that should govern in caring for them and to indicate the means best fitted for putting these principles into effect.

Convalescence is a period of transition from sickness to health; a period which, under favoring conditions, can be shortened and, besides, the health of the individual more firmly established. The proper surroundings, the kind and the degree of care and the intelligent oversight that are necessary in order to secure this cannot, in the nature of things, be realized in hospitals for the sick nor, generally speaking, in the homes of the patients themselves, more particularly of the poorer class and those who are in moderate circumstances. These things have been commonly lost sight of. A house in the country, however attractive it may be for well people, is ill adapted to the needs of convalescents because something more is needed in the majority of cases than merely a sojourn out of town. It is concerning these matters chiefly that this report refers.

Although these facts are well recognized, still it is remarkable that more has not been accomplished in the way of making provision for the care of convalescent patients. Homes have been established on no coordinated plan of convalescent relief, without much realization of the various types of convalescence and, in the main, the needs of adult convalescents have received scant attention. No doubt one of the main reasons is that hitherto not enough study has been made of the subject. The subject presents many problems, but these primarily are concerned with the limitations of the term convalescent state, the requirements of the convalescent patient, the different types of patients to be cared for, and the necessary distinctions to be made in the care of them.

DEFINITION

There are two classes of patients in addition to those actively ill for whom special accommodation and care should be available.

Class I. Patients making progress toward recovery from some acute manifestation of disease, but unfitted for a time for full resumption of their duties.

Class II. Dispensary or ambulatory patients with slight or no evidence of organic disease, but with persistent symptoms of functional disturbance which interfere with the proper performance of work.

QUALIFICATIONS

In forming a judgment as to the establishment of the convalescent state, or the fitness of a patient for transfer to a convalescent home, it should be noted that:

1. There should be no probability of an early recurrence of acute symptoms.

2. Fever should be absent and, in Class I, the symptoms should have abated to a decided degree.

3. Strength should be sufficiently regained to enable the patient to be up and about to at least a moderate degree and be able to stand the necessary journey.

4. Patients should not be in need of any medical or surgical attention other than the suitable routine care provided by the respective institution.

5. Patients should be oriented as to time and place and the physical as well as mental state be such as to render them amenable to the convalescent home's discipline and not a source of disturbance to other patients.

6. As far as can be determined patients shall be in such condition as to make the danger of communicating a disease to others unlikely.

THE NUMBER OF PATIENTS ANNUALLY IN NEED OF CONVALESCENT CARE

There are no figures available for a statement of the number of medical cases requiring convalescent care. The medical services of Bellevue and Allied Hospitals contain 490 beds and these, according to the hospital survey of the Public Health Committee of the New York Academy of Medicine, constitute approximately one seventh of the total medical bed capacity of Greater New York, given as 3,319[1]. A rough estimate can therefore be made of the total number of medical cases discharged annually from New York hospitals by using the Bellevue and Allied Hospitals' Reports as a basis for calculation. The average number of medical cases discharged annually from the Bellevue group based on reports of the last decade is 8,000. A further analysis of the Reports permits of an arbitrary grouping as follows: Cardiovascular disease, 1600 or twenty per cent.; respiratory disease, 3,600 or forty-five per cent.; dietetic disease, 1,466 or eighteen per cent.; others, 1,380 or seventeen per cent. Multiplying 8,000 by seven gives then a general idea of the total annual medical discharges. The percentage of these discharged patients requiring and desirous of convalescent care is even more problematical. It has been estimated that fifty per cent. of all discharged heart patients should have the advantage of convalescent care; in another group selected, diabetics, the estimation is thirty three per cent. Taking a low estimate of twenty five per cent of all discharged medical patients would mean a total of 14,000 annually distributed as follows: cardiovascular, 2,800; respiratory, 6,300; nephritis, alimentary and metabolic, 2,520; others, 2,450. If two weeks may be considered the average length of convalescent treatment, this gives a figure of twenty six patients to each bed annually; for 14,000 patients a

[1] *The Hospital Situation in Greater New York*, G. P. Putnam's Sons, 1924, p. 75.

total bed capacity of 540 is required. This estimated convalescent bed requirement represents a minimum in that it applies only to patients discharged from hospitals. In addition to these are to be considered patients in attendance at dispensaries and those taken care of in private practice. No figures whatever are available concerning these two groups. In the Public Health Committee hospital survey the total convalescent bed capacity on the annual basis is given as not over 2,650, of which almost two thirds are for children under sixteen[2]. This leaves, therefore, 880 beds for adults; the beds for purely medical cases would be much fewer in number. It is obvious, therefore, that the supply is far below the present demand. As convalescent homes become better organized and their purpose and effectiveness better known to the public, the demand will become greater. At the present time the proper step is to organize and classify the existing homes, to determine which of these shall deal with medical cases, and to arrange that these latter provide for types of patients in proportion to their numerical ratio. With the proper system in force and the need of homes thoroughly understood the supply should gradually approach the demand.

CLASSIFICATION OF CONVALESCENT PATIENTS

Any comprehensive plan for convalescent homes must be based on a definite classification of patients. Convalescent patients are classified first, according to the type of disease, and, second, according to social or personal status.

It is of the first importance in promoting convalescence that full consideration be given to the character of the antecedent disease, or the nature of the underlying cause since convalescent homes must make provision for the carrying on of definite principles of therapy, diet, exercise and regimen appropriate to each class. Convalescent patients are classified as to type of disease as follows:

1. Cardiovascular.
2. Dietetic.
3. Respiratory.
4. General infections and miscellaneous.

Of the total number of medical patients discharged annually about twenty per cent. are classed as cardiovascular cases; over two thirds of these are cases of true heart disease. Thus of all discharged medical cases, twelve or fifteen per cent. would be included in the first type. Taking cognizance of the fact that patients having the arteriosclerotic forms of disease are in the majority, and that these patients are less frequently benefitted by convalescent care than those suffering from the infectious types of heart disease, it is estimated that fifty per cent. of all heart patients discharged should have the advantage of convalescent care. This means between six and seven and one half per cent. of all medical discharges.

Under the second type are included those patients who will require special dietetic supervision. These are divided into three groups: 1, diabetics; 2, nephritics and those with dietetically related diseases and conditions; 3, those convalescent from disease of the alimentary tract.

The diabetic group includes adolescent and adult diabetes, but not the aged with mild diabetes. This group comprises about two per cent. of medical discharges. Estimating that one third of these should have convalescent care, this means 0.6 per cent. of the total discharges.

The nephritic group includes patients convalescent from the several varieties of nephritis in which nephritic symptoms have predominated, convalescents from scarlet fever, arteriosclerotics (without paralysis), the aged, and patients with high blood pressure. It does not include the socalled cardionephritics in which symptoms of cardiac decompensation predominate. The nephritic group forms about seven per cent. of medical discharges. It is estimated that half of this group, or three and one half per cent. of medical discharges, should have convalescent care.

The group convalescent from alimentary disease includes patients recovering from acute or chronic gastritis, peptic ulcer, dysentery, mucous and ulcerative colitis and severe diarrhea of unknown nature. The socalled visceroptosis patients are not included. This group forms about nine per cent. of medical discharges. Probably one half will require convalescent care, or four and one half per cent. of the total medical discharges.

Under the third type is included convalescents from respiratory disease. They are placed in a special group because of the possibility of infection to others, annoyance to other patients from cough, and the special facilities and supervision required. Bronchiectasis cases are excluded on the grounds that they are chronic cases, although there may be exceptions to this. Asthmatic cases are included only if the determining factor is a bronchitis. Emphysema is also excluded, particularly the senile type. All other of the lower respiratory cases are suitable for convalescent treatment. Consideration should be given to patients recovering from the minor as well as the major manifestations of respiratory disease, more particularly those with short, though sometimes very intense course followed by severe depression, the socalled influenza group.

In estimating the number of this third type difficulties arise. Respiratory diseases are much more often of an epidemic character, and minor epidemics occur so irregularly that it is difficult to arrive at a normal annual average. In providing for this group it must be borne in mind that respiratory diseases are generally limited to a period of six months in the year. A rough approximation of this group would be fifty per cent. of all discharged patients. Probably one half of these, or twenty five per cent., of all discharged patients would avail themselves of convalescent care.

The fourth type is made up of a heterogeneous group not included in any of the others. Numerically, this group constitutes about seventeen per cent. of discharged cases and probably one third or six per cent. would apply for convalescent treatment. On the basis of the estimations given of the medical cases, suitable for convalescent care, the cardiac group would constitute fifteen per cent., the dietetic twenty per cent., the respiratory fifty three per cent. and the miscellaneous twelve per cent.

[2] *The Hospital Situation in Greater New York*, G. P. Putnam's Sons, 1924, p. 287.

Of equal importance with the classification of patients according to the type of disease is the consideration of the social or personal status of patients. Certain racial, religious and social distinctions must be made in order to obtain suitable environment, since this is much more important for convalescent patients than for those acutely ill. Convalescent patients are classified as to social or personal status according to:

1. Age. Provision should be made for the separation of adolescents. Separate homes may be established for this group with provision for each type of disease, but it is more practical to include it with the adult group with a unit separation. Adolescence is arbitrarily fixed between the ages of twelve and eighteen, i. e., from the thirteenth to the seventeenth year, inclusive. Patients over eighteen and up to midlife might advantageously be placed in another group, while those of more advanced age might be put in a third group.

2. Sex. As is the case with general hospitals, there is no necessity for establishing homes for one or the other sex exclusively. Under proper control, a mingling of the sexes in a convalescent home is desirable.

3. Color. Homes for negroes only would be advantageous in many ways. There is difficulty, however, in the matter of establishing and financing such homes. The question of accepting negro patients and arranging for their accommodation in the convalescent home is one for the management of each institution to solve.

4. Religion. With regard to the religious status of patients a distinction is necessary only so far as it concerns dietetic management for orthodox Hebrews. The number of this group of patients is relatively very small, and additional special homes for the group seem unnecessary.

5. Mothers with dependent children. The problem of providing for convalescent mothers with dependent children is a difficult one. During the mother's stay in the hospital arrangements for taking care of her children are made by relatives, friends or the hospital social service. These arrangements may be carried on during the convalescent period. In some instances, however, this may be impossible, and it would be of great advantage to have homes for mothers in which a limited number of well children may be cared for.

6. Ability to pay. Finally, it is desirable that homes be established for convalescent patients who are able and willing to pay a moderate sum for maintenance. The amount obtained from this source would help the home materially. Many patients are able to pay from seven to fourteen dollars a week and in so doing they preserve their independence and are saved the feeling of being recipients of charity. All patients who have been treated in private practice would be expected to pay toward their maintenance. There could be admitted into this group selected patients who pay nothing, but who, through social status and congeniality, fit in well with the pay group. The pay homes from the viewpoint of convalescent care, should conform to the free homes in their provision for the different types of patients received.

CLASSIFICATION OF CONVALESCENT HOMES

The application of the classification of convalescent patients necessitates corresponding classification of convalescent homes. From the viewpoint of type of disease, homes should be established to provide properly for each of the four types mentioned. One home may be arranged for a single type, and for ease of management and the welfare of the patients, this would be a desirable provision. A larger home may consist of a number of units with provision for each type, and while this would make the management more complicated, it would be preferable financially.

GENERAL RECOMMENDATIONS

1. Convalescent homes should be situated preferably outside the strictly urban district but within such distance as to be readily accessible by rail, trolley or bus; a rural location in general would seem preferable to a seaside one, although the latter has its advantages.

2. The home should be designed according to the cottage system. It may be made up of one or more cottage units, each unit having a maximum of fifty or sixty beds arranged in single rooms and two, three, and four bed wards.

There should be adequate bathing and toilet facilities, reading and recreation rooms, proper heating, open porches with screens, a central assembly room and dining room; these latter should be connected by a covered passageway if they are situated in a separate building. A gymnasium is a desirable feature of a convalescent home.

3. A daily schedule should be enforced, hours for rising and retiring, for meals, occupation and recreation being designated.

This schedule must be prescribed under medical direction as it will vary according to the physical condition of the patient and the type of the disease from which the patient is convalescent. The various chores that may be required of the patient should be included in the amount of occupation prescribed.

Recalcitrant or objectionable patients should be discharged and sent either to their own homes or returned to the institution whence they came. Convalescent homes should accept patients from hospitals or their homes with the distinct understanding of this rule, due notice being given, however, to the hospital concerned when such action is necessary. It is a responsibility incumbent upon a convalescent home to see that patients maintain proper social relations and conduct.

4. Certain principles of treatment are necessary for convalescent patients. Through a central clearing agency all patients should be sent to the homes best adapted for their needs. On arrival they will be examined by the physician in charge and a proper regimen prescribed. The outlined regimen embraces the time of rising and retiring, rest hours, physical exercise, walking, gymnasium work, games, or setting-up exercises, social diversions of various sorts, a properly balanced, attractive and appetizing diet. Special efforts should be made to impress habits of personal hygiene such as the care of the teeth, daily regulation of bowel movement, and general bodily cleanliness. Visits should be regulated.

(To be concluded)

Book Reviews

DISEASES OF THE STOMACH

Diagnostik und Therapie der Magenkrankheiten. Von Professor Dr. I. Boas. Mit 145 Textabbildungen und 6 Farbigen Tafeln. Leipzig: Georg Thieme, 1925. Pp. 817.

The well known classical book of Professor Boas on the diagnosis and treatment of diseases of the stomach has just appeared in its eighth and ninth editions. New important material has been added and some chapters have been entirely rewritten. Boas recognizes the great value and help of x rays in the diagnosis of digestive diseases, which should be applied in all cases in which the disease cannot be easily recognized. Whenever the diagnosis can be definitely made out by the usual clinical symptoms and laboratory methods, x rays may be omitted.

With regard to the symptom complex of hyperchlorhydria and its connection with duodenal (or better, peptic) ulcer, Boas does not accept Moynihan's view that hyperchlorhydria is duodenal ulcer. Boas rather contends that hyperchlorhydria or superacidity can exist for a long time as a mere functional disturbance of the stomach, without any organic lesion. Combinations of the two lesions, however, are a frequent occurrence. Treatment with alkalies plays an important rôle in the management of peptic ulcer and also superacidity. Boas does not favor the domination of alkalies at the height of digestion, for according to his experience it rather increases the flow of gastric juice. When the alkalies are given shortly before meals and not in too large doses they exert a beneficial effect and rather diminish the acidity.

The specialist as well as the general practitioner will find no end of useful information on almost every page of this unexcelled book, written by the greatest living expert on gastroenterology.

PATHOGENESIS OF GALLSTONES

Pathogénie des Calculs Biliaires et Indications Opératoires. Par Thorkild Rovsing. Traduction du Dr. Saint-Cène. Paris: Masson et Cie, 1925. Pp. 1925.

In this excellent monograph, translated by Dr. Saint-Cène from the Danish, Rovsing refutes Nounyn's well known theory regarding gallstones. According to Naunyn all gallstones form in the gallbladder on the basis of infection and bile stagnation. Rovsing's large experience, covering thirty years and over five hundred and fifty gallstone cases in which he operated and minutely analyzed the findings, seems to show that the formation of gallstones begins in the small biliary canals of the liver. The process is as follows:

Through a transient toxemia, black calcium bilihumine is formed by the liver cells and thrown into the fine capillary biliary canals. Soon small irregular concretions of calcium pigment with rough surfaces are formed. These tiny concretions reach the gallbladder, often massing together on the way to this reservoir. There, due to their rough surface, they stick to the mucous membrane and grow through precipitation from the bile of cholesterin, calcium bilirubin, and calcium biliverdin, which is cemented together by an organic mucous secretion of the epithelial cells of the gallbladder mucosa. The growth of the calculi is hastened by the concentrating quality of the gallbladder for its bile content and by an undue increase of cholesterin either by cholesterin rich foods or by disease processes manufacturing larger quantities of cholesterin. In a great number of instances the calculi remain in the gallbladder without doing much harm. So soon, however, as the biliary calculi begin to migrate from the gallbladder into the cystic or common duct then morbid symptoms appear. Severe pains (colic), fever, jaundice, and various dyspeptic phenomena make their appearance. At this stage there are already secondary infectious processes present, which, if not checked, may lead to cholemia, empyema, and gangrene of the gallbladder. The best treatment for these active conditions is surgery, removal of the gallbladder with its offending material. The book is herewith highly recommended.

VITAMINES

Theorie des Vitamines et ses Applications. Essais de Vitaminologie par Jean Lorenzini. Avec Préface de Charles Richet. Paris: Masson et Cie, 1925.

This little volume, it is hardly more than a brochure, contains an admirable study of the vitamines and their rôle in nutrition and growth. It is based on a large series of experiments on animals, notably pigeons and guineapigs, and on clinical study of a series of cases of scurvy, infantile rickets, and Barlow's disease. Lorenzini notes that lack of vitamine B may produce symptoms of multiple neuritis in chickens and pigeons, and of scurvy in guineapigs. This avitaminosis seems to have a special affinity for the nervous system, by way of general nutrition. The rôle of the antirachitic vitamine in fixing clacium salts to bone cells, is confirmed. It is probable that the vitamines are complex bodies with reactions in the sphere of metabolism of proteins, fats, and carbohydrates, and in the field of dyscrinisms, as well.

PROCTOLOGY

Treatise on the Diseases and Injuries of the Rectum, Anus, and Pelvic Colon. By J. Rawson Pennington, M.D., F.A.C.S. With Two Plates and 677 Illustrations. Philadelphia: P. Blakiston's Son and Company, 1925. Pp. 933.

This comprehensive volume of over nine hundred pages is a worthy contribution to proctology. The work is divided into three parts. In the first, the general principles of proctology are outlined, the author's well known concept of the splanchnosomatic funnel being described in detail. The only possible criticism of this part is that the section on anamnesis could probably be expanded with advantage.

The next two parts deal with the diseases and injuries of the rectum and anus, and with diseases and injuries of the pelvic colon respectively. These contain a mass of special information bringing the subject down to the presentday point of view in every particular.

The presentation of the material is novel. A general historical introduction precedes the text and each chapter is headed by a historical summary of its own. At the beginning of each chapter also are a couple of excellent portraits of men who have contributed not-

ably to the development of proctology. The illustrations, of which there are well over six hundred, add greatly to the value of the text.

The style is choppy and at times unconventional, but these peculiarities seldom if ever lead to unclearness of expression.

The book will undoubtedly meet with immediate success, as it is easily the best modern American one volume treatise on proctology.

DIAGNOSIS OF NONTUBERCULOUS DISEASES OF THE LUNGS

Die Nichttuberkulösen Lungenerkrankungen im Roentgenbilde. By Dr. Max Cohn. "Würzburger Abhandlungen aus dem Gesamtgebiet der Medizin." Leipzig: Kurt Kabitzsch, Band I, 1924, Heft 10.

This contribution is of interest not only to those who work in the x ray laboratories, but to all who resort to fluoroscopic and x ray examinations in their daily practice. In the introduction the author very wisely remarks that when one does not endeavor to read out of the Röntgen picture more than is rationally possible then the differential diagnosis with the help of the x ray apparatus is of greatest value. In this booklet of eighty pages is given a description and illustrations of croupous pneumonia, bronchial pneumonia, pneumonia following influenza, pneumonia in childhood, also of lung infarct, asthma, bronchiectasis, and the various pneumoconioses. Most interesting are the descriptions and pictures of the rather rare cases of echinococci. The final chapter describes and illustrates abscesses, neoplasms and foreign bodies occasionally found in pulmonary tissue. This volume gives in a concise way the differential diagnosis which, without the x ray picture, in many instances would seem most difficult. It is to be hoped that some enterprising young physician familiar with the German language may honor this valuable contribution by translating it into English.

CANCER

Tumors and Cancers. A Biological Study. By Hastings Gilford, F.R.C.S., formerly Hunterian Professor, Royal College of Surgeons of England. With an Introduction by Sir Frederick Keeble, C.B.E., Sc.D., F.R.S., Regius Professor of Botany at Oxford University & Fellow of Magdalen College. London: Selwyn & Blount, Ltd., 1925. Pp. xii-703.

In spite of the numerous exhaustive studies on tumors and cancers in man, lower animals, and plants, from every possible known aspect, the question of their etiology remains unsolved.

In this book the author has collected all the various views on the sources, genesis, nature, ecology, prognosis, prevention and treatment of tumor growth and disposes of them in an orderly and philosophical manner. The influence of age, diet, reproduction, and civilization on cancer, and the history, diagnosis and structure of these growths are discussed in great detail.

The ultimate cause of cancer seems to be senescence—of the cell, the tissues, and the body. The impression is given that cancer is a disease of disordered growth, due to "degeneration of human material" incident to modern civilization, which is to be combated by a change in our mode of living. Chief among these degenerative tendencies are the cultivation and propagation of degeneration in our schools for defectives, our lunatic asylums, our hospitals, and our other philanthropic institutions; inadequate use of various organs, weakening them and predisposing them to degeneration. Among the organs chiefly affected by the atrophy of disuse are the entire alimentary tract and the reproductive organs.

Nothing new is presented in this massive volume, but it is stimulating reading, and the author's style makes it most interesting. It is an orderly and masterly presentation of the entire subject of neoplastic growth. The bibliography and index of subjects are very extensive.

EXPERIMENTAL PHARMACOLOGY

Einführung in die Pharmakotherapie. Für Mediziner and Naturwissenschaftler. Von Reinhard von den Velden, a. o. Prof. an der Universität Berlin, und Paul Wolff, Dr. med. et phil.-Berlin. Leipzig: Georg Thieme Verlag, 1925. Pp. viii-200.

The knowledge of experimental pharmacology is not generally applied by the general practitioner at the bedside. Chemists and pharmacists engaged in the investigation and preparation of drugs, on the other hand, have not the fundamental knowledge of pharmacotherapy. The usual textbooks offer no assistance in this matter, as they are intended primarily for the theorist or the practitioner. This book is intended to serve as an intermediary and to combine therapeutic indications derived from pathologicophysiological observations with the application of knowledge derived from experimental pharmacological experiences.

The book is divided into three parts in conformity with the three fundamental functions of the body: the repelling of disease, nutrition, and propagation. Pharmacotherapy is nothing else than an attempt to restore disturbed function, not only from the narrow view of symptomatic treatment of the smallest cell complexes, but according to the larger viewpoint of the entire organism. In this way the narrow field of symptomatic treatment is broadened.

The first section deals with the pharmacotherapy of the skin, mucous membranes, tissues, the respiratory system and the uropoietic system. The second section includes the treatment of diseases of the digestive canal, intermediary metabolism, the circulatory and nervous systems. The third section has reference to the genital system of both sexes.

PHYSICAL DIAGNOSIS

A Manual of Physical Diagnosis. By Austin Flint, M.D., LL.D., Ninth Edition, Revised by Henry C. Thacher, M.S., M.D. Illustrated. Philadelphia and New York: Lea & Febiger, 1925.

The fact that this little volume appears in its ninth edition is significant of its value. The importance of a thorough knowledge of physical diagnosis, an art which is frequently slurred over by those for whom the x ray and similar laboratory aids have opened up what is looked upon by them as a short cut in clinical diagnosis, cannot be sufficiently stressed. The x ray and the electrocardiograph, while important in confirming bedside findings, will never take the place of auscultation and percussion or a careful clinical estimate of the physical condition of the patient's heart and lungs. After all they are but ma-

chines. The x ray frequently portrays shadows which need for their ultimate diagnosis a proper physical examination. The electrocardiograph often gives us no information of myocardial damage, which, on the other hand, clinical, bedside observations and physical findings will alone reveal. As aids in diagnosis, the value of laboratory methods should not be underestimated. Each should supplement the other, and one ought not be neglected at the expense of the other.

In the practice of medicine where laboratories are not available, a thorough knowledge of physical signs is of paramount importance. The undergraduate as well as the graduate in medicine will find in Flint's *Manual,* stated in a succinct and clear manner, the methods of physical examinations beginning with inspection, palpation, percussion and auscultation. The chapters dealing with the diseases of the chest and cardiac irregularities are especially to be recommended. Early diagnosis of pulmonary tuberculosis is often a matter of physical examination only and that phase is thoroughly exposed. In addition many other features, such as the diagnosis of thoracic aneurysm and various abdominal conditions, are presented with a simplicity and directness which will repay a most serious consideration of this invaluable work by the internist.

THE FIXATION TEST IN TUBERCULOSIS

La Reaction de Fixation dans la Tuberculose. By Achille Urbain. Paris: Masson et Cie., 1925. Pp. 129.

The value of the fixation test in tuberculosis is still a disputed subject, but this author tries to convert the opponents to its adoption by a carefully prepared monograph in which he defends his thesis. He gives an accurate description of the necessary elements to obtain the reaction in the first chapter. The second chapter deals with the technic; the third with the tuberculous antibodies; the fourth with the application of the reaction in the fixation test as a means to diagnose tuberculosis in human beings; the fifth with the reaction as applied in the fixation test as to diagnosis of tuberculosis in animals. In the concluding chapter the author quotes the opinions pro and con on the value of the fixation test by other authors. He admits that Armand-Delille, Hillemand and Lestoquoy at the meeting of the Hospital Society of Paris reported unfavorable results with the test and came to the conclusion that it would not be wise to rely on the fixation test, whether positive or negative, without clinical corroboration. Aviragnet and Goldenberg reported as a result of fixation tests ninety per cent. positive reactions among the tuberculous having bacilli, and ten per cent. positive among the clinically diagnosed tuberculous in whom bacilli were not found. The author himself reports the most striking results obtained in the diagnosis of bovine tuberculosis and tuberculosis in carniverous animals. In the former he reports ninety to ninety-eight per cent. negative results in absolutely healthy animals. In the carnivorous animals, where tuberculin tests give satisfaction, the author maintains that the fixation test gives far greater satisfaction than any other known method of diagnosis. The book is to be recommended to all laboratory workers connected with sanatoria and to all persons interested in tuberculosis research work.

DUCDAME

Ducdame. By John Cowper Powys. Garden City: Doubleday, Page and Company, 1925. Pp. 458.

This is the first intelligent book on the decadence of the English aristocracy that we have read. It makes no attempt to rescue its characters or put them in any especially good light. tI does not even point the outcome or the cure. It shows a group of people moving in an orbit decreed by centuries gone by. Their acts are quite beyond their control. They are ancestrally "determined."

The *dramatis personæ* are somewhat unreal to the American imagination. The old order has produced two sons, Rook Ashover—now Squire—and his invalid brother. The aged mother's one concern is that the family name shall not die. For years the members of the family have been struggling like insects in a web against the dimly felt futility of their existence. And finally Rook, his mother's only hope, brings home a woman who will not marry him, whom he in his effort to be himself sees no need of marrying. Moreover, she cannot bear him a child. All efforts are now turned to displace the mistress, and entangle Rook with his suitable cousin. The mad vicar and his pliant wife with whom both Ashovers have intrigued, add to the tensity of the story. Throughout runs the breath of stagnation, of a pocket on the earth's surface where the dead are more real than the living.

The struggle for survival of the family is won. A son is conceived. A marriage is perpetrated. There is no further need of the male spider. He dies. And with Rook's passing, the invalid brother begins to thrive. The curse is lifted from him. He no longer has to worry himself into a decline over the perishing of the name of Ashover.

One factor the book has that will make it of importance to readers not so interested in the morbid interplay of the story. The pictures of seasons, of English atmosphere, of tenuous landscape effects so foreign to us, and so imbued in the English soul, are unexcelled. There is a good deal of Nature in the book, a subtle undercurrent to show how the violation of Nature's laws brings rapid destruction.

Medicoliterary Notes.

The Danish National Board of Health supervises the food of inmates of public institutions, basing its regulations on nutritional studies and on national diet habits and customs.

* * *

Short stories for summer reading by entertaining writers are *Mayfair,* by Michael Arlen; *Caravan,* by John Galsworthy; *Bring! Bring! and Other Stories,* by Conrad Aiken; *Mr. Bisbee's Princess,* by Julian Street; *Georgian Stories for 1925,* a collection containing tales by Arlen, Martin Armstrong, E. M. Forster, Aldous Huxley, F. Tennyson Jesse, C. E. Montague, J. C. Squire and others; and *The Old Woman of the Movies,* by Blasco Ibanez.

* * *

Mariemont, Cincinnati's garden village, is nearing completion. Nearly one hundred families have moved in and are enjoying their new homes which combine beauty, sanitation and convenience in a very practicable manner. The idea was conceived and worked out by Mrs. Mary M. Emery, a citizen of Cincinnati.

* * *

Announcement has been made that David Binney Putnam, twelve year old son of the publisher, George Palmer

Putnam, is writing a book to be published in the fall about his voyage with William Beebe on the Arcturus. The title will be *David Goes Voyaging*, and it will have many pictures from photographs.

* * *

The leading editorial in the *Nation's Health* for May is a tribute to Dr. William H. Welch of Johns Hopkins, who recently celebrated his seventy-fifth birthday. It characterizes him thus: "His is a name which, like Osler's, stands rather for a personality, for a ripe wisdom and a rare spirit which have found expression in stimulus and encouragement and guidance for a thousand men and a score of great achievements."

* * *

Recent publications of interest to the medical profession are *The Mental Growth of Children in Relation to the Rate of Growth in Bodily Development*, a report of the Bureau of Educational Experiments, by Buford J. Johnson (Dutton); *Psychology for Child Training*, by Arland D. Weeks (Appleton); *Handbook of American Prisons*, by the National Society of Penal Information (Putnam); *Bibliography of the Writings of Sir William Osler*, compiled by Minnie Wright Blogg (Lord Baltimore Press); *Modern Medical Methods*, by Haydn Brown (Andrew Melrose); *Mental Disorder and the Criminal Law*, by S. Sheldon Glueck (Little, Brown); *The Mental Growth of the Preschool Child*, a psychological outline of normal development from birth to the sixth year, including a system of developmental diagnosis, by Arnold Gesell (Macmillan); and *Things and Ideals*, essays in functional philosophy, by M. C. Otto (Henry Holt).

* * *

In a recent number of the *Survey* attention is called to an important but greatly neglected problem—the provision of adequate care for the chronic and convalescent. There are only about ten thousand convalescent beds in the United States, so an increase in their number is of the greatest importance. Such an increase would make two significant contributions to medical care and treatment, namely, it would provide facilities for cases now being improperly cared for in their homes; and second, it would relieve the hospitals of the burden of caring for cases which do not actually need hospital treatment with all its many and large expenses. The article states: "By providing the comparatively inexpensive facilities for the proper care of these two types of patients, many communities can postpone for a considerable time the building of costly hospitals which seem necessary at a casual glance to meet the present need, and can ensure the most effective and lasting results from the use of hospital facilities already in existence."

* * *

To provide for a group of fellowships in neuropsychiatry with special emphasis on child guidance work, the Commonwealth Fund of New York City has granted to the graduate school of medicine of the University of Pennsylvania the sum of $12.000 for three years. . . . A physician in order to be eligible must present the following minimal qualifications: 1. age from twenty five years to thirty five years inclusive; 2, graduate of a class A medical school; 3, one year's approved internship; 4, satisfactory references; 5, approval of personal and professional status. Each fellowship will be granted upon the basis of three years' work —one year in basic sciences, one year of clinical work in neurology, psychiatry, and child guidance, and one year of clinical research in the field of child guidance. . . . *Mental Hygiene Bulletin.*

* * *

The Republic of Chile, by a single stroke of legislation, has created a Division of Social Hygiene which has police power for the enforcement of preventive measures. It has for its function the dissemination of information about venereal diseases, the creation of social hygiene professorships, and the suggestion of types of elementary school instruction in social hygiene. It is further vested with the power to repress and control prostitution. Any woman prostitute declared to have venereal disease is to be confined to a hospital during the period of contagion. Those refusing treatment are to be sent to a reformatory. Provision is also made for injunction and abatement measures making it possible to close up as a nuisance any building which the owner permits to be used for purposes of prostitution. Advertisements relating to patent medicines for the cure of venereal diseases are not to be accepted for publication in newspapers and magazines, unless endorsed by the Division of Social Hygiene. A medical certificate of good health is required from both men and women before marriage.

* * *

An editorial in a recent number of the *Nation's Health* comments upon the fact that because we are civilized it does not necessarily follow that the conquest of preventable disease is accomplished. The very progress of civilization itself is constantly creating new dangers. Wild beasts and poisonous snakes no longer threaten human life on a large scale except in India, and famines and floods are now restricted to Russia and Japan; such plagues as typhus and the Black Death, due to insanitary living, no longer afflict civilized lands, and the intestinal diseases, such as cholera and typhoid fever, seem likely to follow them into the category of medical curiosities. On the other hand acute respiratory diseases, caused by urban life, widespread travel, overheated homes, schools and working places; dietary diseases from artificially refined food, and over eating; rickets from living without sunlight; lead and carbon monoxide in factories, homes and garages; and, last but not least, automobiles upon our highways, take a heavier toll of life than ever tigers or bears could account for.

* * *

The National Committee for Mental Hygiene announces that it has for distribution the following new publications: *Should Nurses Do Intelligence Testing?* by Dr. Frankwood E. Williams; *Changing the Child's Behavior*, by Phyllis Blanchard, Ph.D.; *The Application of Psychiatry to High School Problems*, by Dr. Anne T. Bingham; *Drug Addiction in Its Relation to Crime*, by Dr. Lawrence Kolb; *Standard Neuropsychiatric Veterans' Hospital*, by Dr. Samuel W. Hamilton; *Demonstration Child Guidance Clinics*, report of the Division on Prevention of Delinquency of the National Committee for Mental Hygiene; and Purposes and Activities of the National Committee for Mental Hygiene.

* * *

The cancer rate is very high in Switzerland, second only to that of Denmark, and, among the chief factors in Swiss mortality, cancer ranks third, following tuberculosis and infant mortality, and ahead of the acute respiratory diseases.—*Bulletin of the Office Internationale d'Hygiene Publique.*

* * *

The increased and increasing interest in health is shown by the large number of articles on the subject appearing in popular publications. Among them are the following: Elderly Athletes—Remember, You're Not a 1925 Model! by William Hemmingway in the *Saturday Evening Post;* Fair, Fit and Forty, by Clara Bell Thompson, ditto; Have You Been Vaccinated Lately? by L. D. Parlin, in *Collier's Weekly;* The High Cost of Babies, by Ida L. Allbright, in the *Atlantic Monthly;* Light Refreshments, by Dr. Woods Hutchinson, in the *Saturday Evening Post;* Make Your Sport Fit Your Age, by Walter Camp, in *Collier's Weekly;* and Three Times a Day, by Myron W. Stearns, also in *Collier's. The American Journal of Public Health*, from which this list is taken, suggests that health workers write the editors regarding the articles they publish, commending the good and calling attention to the bad—and adds, "Please send a carbon of your letter to the editor of this department (Education and Publicity) of the *Journal.*"

* * *

Edwin Valentine Mitchell, bookseller and publisher of Hartford, Connecticut, announces that he will publish in the autumn a one volume selection of the best cases from that famous old chronicle of crime, *The Newgate Calendar*, with the original illustrations.

* * *

A recent industrial report states that no employee of the cinnamon warehouse connected with the docks of London (England) has ever had influenza.

* * *

Two articles of special interest in the *Nation's Health* for June are Points in Preventive Psychiatry, by Dr. Edward A. Strecker of the Mental Hygiene Division of the Public Charities Association of Pennsylvania; and Irritations of the Skin Due to Industrial Causes, by Dr. Guy C. Lane, assistant dermatologist in the Massachusetts General Hospital, Boston.

Abstracts from Current Literature

GASTROENTEROLOGY

Studies in Gastric Analysis.—Richard T. Ellison (*American Journal of the Medical Sciences,* April, 1925) presents the following results:

1. Simultaneous fractional gastric analysis from two points in the stomach definitely fixed ten cm. apart produce curves that are entirely similar in their general characteristics except where influenced by biliary regurgitation. The acid values from the antrum are always higher than those from the fundus except where the former are cut by biliary regurgitation. With the bread and water meal there is a tendency for the acid values of the two parts to become equal during the second hour due to the diffusion of the acid through the fluid meal.

2. There is a recognizable difference in the physical properties of the extractions from the fundus and the antrum, this change being due to the comminution of the test substance by the peristaltic activity of the antrum. If this comminution is not found in extractions from the antrum it is evidence that the stomach is not doing a portion of the work it normally should do.

3. The antrum, close to the pylorus, is the best place to study gastric function, for there the stomach has most nearly completed its work on the test material, and the condition, both physical and chemical, in which the test material will be passed on to the duodenum can best be determined.

4. Fractional analysis when properly performed is of great assistance in the clinical determination of the capacity of the stomach for work under test conditions. It must be firmly kept in mind, however, that the fractional feature of the examination does not refer to the contents of the stomach but rather to the work being done by it. It is only by frequent sample extractions of the result of gastric work that we can form any true conception of the course and completeness of gastric digestion.

5. Biliary regurgitation does not pass beyond the antrum into the fundus and therefore its neutralizing effect does not extend to the large mass of food held there, the acidity of which may continue to rise.

6. Biliary regurgitation cannot be considered primarily as a mechanism to neutralize a high gastric acidity, because its influence does not extend to the whole stomach contents, and because it does occur in the presence of an original low acidity. It seems more probable that biliary regurgitation is an expression of the reverse peristalsis caused by a lesion either directly or indirectly irritating the muscular wall of the intestinal tract.

7. Any change in the position of the tip of the tube during the course of the test alters the curve and defeats the object of the fractional type of analysis.

Partial Gastrectomy in Peptic Ulcer.—W. Wayne Babcock (*American Journal of Obstetrics and Gynecology,* April, 1925) points out that primary gastrectomy for peptic ulcer, while often a tedious and difficult operation, has a low primary mortality, comparing well with that of other radical methods for treating ulcer. Convalescence after partial gastrectomy is, as a rule, as smooth as after a single gastroenterostomy, and there is reason to believe that the secondary morbidity, especially for gastric ulcer, is less. While the best method of resection in gastrectomy remains to be determined, replacement by this procedure of other operations for gastric ulcer is already warranted. In duodenal ulcer the field of partial gastrectomy is more limited; it is, however, the operation of choice in certain cases not amenable to gastroenterostomy. For recurrent ulcer or jejunal ulcer following gastroenterostomy, partial gastrectomy is most valuable. The most physiological type of partial gastrectomy is a modification of the Billroth I. The author describes a procedure with telescopic anastomosis wherein resection of the stomach mucosa well above the line of section of the outer wall of the stomach is carried out in order to increase the effect of the gastrectomy. By this means one can remove more of the ulcer bearing and acid activating portions of the mucous membrane with a smaller gastric resection, and by telescoping the end of the duodenum into the stomach and anastomosing it to the divided gastric mucosa, produce a strong reinforced union. Guide sutures are so introduced as to connect the upper and lower borders of the stomach and duodenum two or more centimetres distant from the line of proposed section, and are used to stretch the duodenum against the wider posterior face of the stomach. The gastric sutures are spaced about three times as widely as the duodenal, so that the two tubes are made to fit in end to end fashion. The author has used partial gastrectomy for ulcer or its complications twenty-five times without any operative mortality.

Peptic Ulcer and Palpable Masses.—Howard R. Hartman (*Medical Clinics of North America,* January, 1925) states that a history of gastric complaint and a palpable mass in the upper abdomen is almost dagnostic of gastric cancer, as ninety five per cent. of such masses prove to be malignant. Occasionally, however, an accurate x ray examination which reveals a benign lesion, may substantiate the clinical history so that a diagnosis of peptic ulcer, with an inflammatory mass, can be made. This differential diagnosis is of great importance to the patient because operative interference, if undertaken too soon and without the proper preparation of the patient, is likely to prove fatal. If the patient receives proper and ample preoperative preparation, the inflammatory masses subside and operation is then conducted without the danger of infection and the too frequent sequelæ. To arrive at the correct diagnosis in such cases, one must weigh all the clinical evidence and not forget the high incidence of malignancy, but if the patient's general condition is good, the classical indications of carcinoma are lacking, and there is clinical evidence to support the diagnosis of ulcer, one is justified in the diagnosis of an inflammatory condition subsequent to ulcer, particularly if confidence can be placed in the x ray diagnosis.

Gastric Carcinoma.—Martin E. Rehfuss (*Medical Clinics of North America,* November, 1924) emphasizes the importance of the earliest possible recognition of carcinoma of the stomach by the physician, as all surgical statistics prove that if the diagnosis is made sufficiently early, life can be prolonged and even saved. In spite of irradiation therapy, the knife is the only cure for carcinoma of the stomach in the present state of our knowledge. The following suggestions are offered:

ROENTGENOLOGICAL EXAMINATION

1. This should include careful fluoroscopic study not only in the anteroposterior position, but the lateral one as well, so as to disclose lesions on the anterior and posterior wall.

2. An examination in the recumbent position is necessary in all doubtful cases to reveal lesions in the cardia as well as to visualize the pylorus more perfectly.

3. A small diffuse gastric lesion may fail to reveal its presence on x ray examination, but in ninety-five per cent. of cases the lesion gives roentgenological evidence of its presence.

4. Always suspect a negative defect in the stomach even though it has the dimpled appearance of healed ulcer.

5. Carcinoma of the stomach ought to be treated like an acute lesion.

6. Healed gastric ulcer ought to be repeatedly rerayed owing to the possibility of malignant transformation.

7. A routine Wassermann should accompany the demonstration of every gastric defect.

8. Sins of commission as well as of omission occur, and where a reasonable doubt exists only repeated x raying and a complete and exhaustive study may enable one to reach a conclusion.

REGARDING GASTRIC ANALYSIS

1. Examine the fasting residuum for retention, microretention, pus, blood, and organic acids. These are the cardinal points in that study.

2. Use a simplified test meal, preferably the Ewald meal, which will reveal pathological exudates.

3. A tendency to generally lowered acid output up to total achlorhydria, the presence of increased soluble protein, the presence of organic acids, a tendency toward the reduction of free hydrochloric acid, and an increase in combined acidity, the presence of an increase in total and combined

chlorin, the demonstration of gastric pus and blood throughout the digestive period, are the important points to be sought.

4. It is now generally acknowledged that in a large proportion of cases of gastric carcinoma, hydrochloric acid is still present, and in the majority of cases of malignant ulcer it reaches a fairly high level.

5. The search for evidence of a congestive, ulcerated, infected lesion is usually performed through a consideration of other factors than acidity.

6. An attempt should be made to correlate these two methods of study in view of the fact that they answer different questions. The x ray answers the questions as to form, position, mobility, and alterations in contour, while gastric analysis points out the alterations in gastric work and the evidence of exfoliation or exudation of pathological products from the diseased area.

Rôle of Blood Chemistry in Diagnosis, Prognosis and Treatment of Obstruction in Upper Gastrointestinal Tract.—Charles S. McVicar (*American Journal of the Medical Sciences,* February, 1925) thus summarizes his paper. With the toxemia of high intestinal obstruction, characteristic changes occur in the chemistry of the blood, namely, a rise in the blood urea, a fall in the plasma chlorids, and a rise in the carbon dioxide combining power of the plasma. By a study of the chemistry of the blood, the condition can be recognized early, the severity can be measured, and the progress of treatment watched. No significant variation has been found in the concentration of the inorganic bases of the blood serum in this condition. Tetany should be considered as a possible severe complication of the toxemia, but severe toxemia may exist without tetany. Tetany may be anticipated when the carbon dioxide combining power of the plasma is found to be above one hundred volumes per cent. The administration of sodium chloride sugar, and water, has been found of value in treatment. All cases show a tendency to alkalosis, and the use of alkali in treatment is contraindicated.

Acute Appendicitis at the Boston City Hospital.—D. Joseph Duggan (*Boston Medical and Surgical Journal,* February 5, 1925) states that the accepted treatment at the Boston City Hospital, once the diagnosis of acute appendicitis is made, is to relax the patient with ether anesthesia, make a right rectus incision in the lower abdomen, incise the anterior layer of the rectus sheath, split or retract the muscle to expose the posterior layer of the rectus sheath which is opened with the underlying peritoneum.

If a simple inflamed appendix is found, a simple appendectomy is done by ligating the mesentery to the appendix, crushing and ligating the base of the appendix, severing the appendix with a knife and cauterizing the stump. No attempt is made to invert the stump. When hemostasis is well established, the cecum is dropped back and the area draped with omentum. The peritoneum and fascia are sutured with catgut. For stay and skin sutures silk worm gut is used.

If an abscess is encountered on opening the peritoneum the intestines are packed off with gauze strips wet with sterile saline solution. The abscess is then opened, exudate bailed out with dry gauze strips and the appendix removed if possible. A drain is placed to the bottom of the abscess cavity.

It is well known that the peritoneum can take care of a considerable amount of exudate. Nevertheless when exudate is found the appendix is drained. The presence of pus in the pelvis is always ascertained by dry sponging with gauze especially when in doubt and there is usually doubt in the acute stage or when periappendicular abscess exists. If there is exudate in the pelvis, a long cigarette drain is inserted in the floor of the pelvis.

If spreading peritonitis is found on opening the peritoneum, the simplest appendectomy is done and the pelvis drained. No mopping or irrigating is done. In these as in all other drained cases the patient is returned to bed and blocks placed to elevate the head of the bed—Fowler's position—for forty-eight hours or longer, depending on the case. The postoperative treatment is important and it varies with the different types of cases. The general principle of treatment of keeping the part at rest is continued by confining the patient to bed, forbidding high enemata and cathartics, and discreetly resuming fluid and food intake beginning with small amounts when all vomiting has ceased.

The removal of drains is still a much mooted question. It is correct to say that as a rule the drain to the appendix stump can be removed safely on the fifth day after operation and the drain to the pelvis on the seventh day.

Stay and skin sutures are removed on the ninth and tenth days after operation. In cases which did not require drainage the patients get up about the twelfth day if there are no complications. In cases where drainage is necessary, the patients are kept in bed a few days after all discharge has ceased because of the possibility of hernia formation through the incision.

Appendicitis: When Not to Diagnose It.—S. T. Irwin (*Clinical Journal,* February 25, 1925) says that if disease of the appendix was missed in days gone by, immunity of the appendix is missed just as often today. Formerly lives were lost through failure to diagnose acute disease of the appendix. Today reputations are jeopardized through failure to exclude it in cases of chronic abdominal or other disease.

Cases of abdominal disease which come to the surgeon with a diagnosis of appendicitis, including by the term both obstructive and inflammatory disease of this organ, may be divided into three groups: 1. Cases in which the diagnosis can be confirmed absolutely. 2. Cases in which the diagnosis can be excluded absolutely. 3. A group of cases where no definite diagnosis can be made and the appendix as a cause cannot be excluded.

In group 3 many of the cases show signs of a general abdominal infection in the form of enlarged lymph glands draining the whole of the area of the small intestine. Some of these can be definitely proved to be tuberculous, with or without obvious ulceration of the intestine. In the case of ulceration it is usually possible to demonstrate some sign of obstruction at the seat of the lesion, but for the purpose of this paper one has not considered these in detail. The main point is that there are many cases with a history of abdominal pain, tenderness over the appendix, and often a prolonged history of ill health, in which the diagnosis of chronic appendicitis has seemed probable, and yet in such cases removal of the appendix produces no material improvement. A genuine chronic appendicitis is comparatively rare amongst the obscure diseases of the abdomen, and to make this diagnosis is often prejudicial to successful treatment, may even be a danger, and always is a stumblingblock to a thorough and systematic examination. Practitioners should hesitate before making the speculative diagnosis of chronic appendicitis.

Intussusception.—As a result of his experiences in twenty cases of intussusception, George M. Gray (*Lancet,* January 10, 1925) states that the treatment of intussusception, provided the child is not moribund, is immediate laparotomy and reduction. The incision preferred is a right paracentral one, because in young children it takes no longer than splitting the rectus, and has the advantage of practically no bleeding and much less risk of hernia. Intussusception cases are also notorious for bursting their wounds five to ten days after the operation, and the surgeon is faced with the duty of sewing up again. Gas and oxygen anesthesia with usually a certain amount of ether is preferred by the author. The state of toxemia makes anesthesia easy. Gas and oxygen alone are never persisted with if there is much straining and protrusion of the bowel; ether is usually given just before sewing up to relax the peritoneum and facilitate stitching.

The mass, if very long, is partially reduced inside the abdomen, and then delivered, and the apical portion is then reduced. The use of a hot saline pad and gentle continued pressure facilitate reduction. If difficulty is still experienced, the introduction of a small artery forceps between the sheath and the entering layer and gentle dilatation help considerably. Hydraulic pressure was used in one case.

In the aftertreatment, all cases were given subcutaneous infusion of glucose, two per cent. in normal saline, immediately after the operation. This helped to lessen the effects of shock. Other points are: 1, that morphine is always given if the child seemed at all restless, and 2, that the child is not starved, being fed four to six hours after operation, if awake. In the more severe cases glucose water, seven per cent., is given for twelve hours before giving milk. The

bowels are opened by small doses of castor oil, if they do not move by the third day. The mortality is considerably reduced by: 1, improvement of the general condition of the child, if bad, by infusion of glucose in normal saline solution; 2, by the prevention of further toxemia and shock by gentle and speedy reduction, gas and oxygen anesthesia, or subcutaneous infusion of glucose in normal saline immediately after operation.

Clinical Review of Intussusception.—Eugene H. Smith (*Archives of Pediatrics,* November, 1924) states that a striking uniformity of symptoms renders the diagnosis of most cases of acute intussusception comparatively easy. The symptoms of sudden onset, pain, vomiting, shock, tumor and bloody stools were present in all of the ten cases reported. Pain is intermittent, with definite and fairly uniform quiescent periods; is usually more severe than that encountered in the commoner digestive disturbances of infancy. Vomiting usually accompanies the pain, and when once established, continues through the acute attack. The degree of shock varies greatly, and it not always proportionate to the extent of the intussusception. Tumor may be located in almost any part of the abdominal cavity; may be superficial or deep; is often movable; may be felt to harden during the paroxysm of pain, and its concavity, when present, is always directed toward the root of the mesentery. Blood passed by rectum in the early stages is brighter and contains less mucus and more watery fluid than is commonly seen in the dysenteries.

Experimental Studies on the Entrance of Bile into the Duodenum.—A. Winkelstein and P. W. Aschner (*American Journal of the Medical Sciences,* May, 1925) state that no evidence was found of spontaneous contractions of the gallbladder in the dog, either under anesthesia or when fully recovered. It is possible to empty the gallbladder by manual expression after the sphincter of Oddi is relaxed, with the peritoneal cavity open or closed. The respiratory squeeze, that is, the increase in intraabdominal pressure at the end of inspiration, also effects an expulsion of bile into the duodenum from the gallbladder when the sphincter of Oddi is relaxed. Direct or reflex stimulation of the gallbladder, whether it be by faradization, drugs, hormones, chemicals, or mechanical means, does not cause a contraction of the gallbladder, or an appreciable change in size, or any emptying, in the experimental animal under anesthesia. In an animal, however, which has fully recovered from the operative procedures, following the instillation of twenty-five per cent. magnesium sulphate or the passage of gastric chyme into the duodenum, and not after normal saline, there is an entrance of bile from the gallbladder into the duodenum.

Whether the more normal physiological conditions in the last instance permit of gallbladder contractions sufficiently strong to expel bile seems extremely doubtful from our experimental observations. It is more probable that certain agents, viz., magnesium sulphate and gastric chyme, relax the sphincter of Oddi and that then, the intraabdominal pressure at the end of each inspiration expresses some bile from the gallbladder into the duodenum.

Gastric Function Before and After Gastrojejunostomy.—T. G. D. Bonar (*Lancet,* August 9, 1924) states that gastrojejunostomy allows the stomach to empty more quickly than usual. The food leaves the stomach through the stoma and in a few cases through the pylorus as well. The rate of emptying is increased, particularly in pyloric stenosis from whatever cause, especially in cases of partial gastrectomy with gastrojejunostomy. Gastrojejunostomy in gastric ulcer reduces the free hydrochloric acid value, but the total acidity remains the same; in pyloric ulcer the hyperchlorhydria persists. In cases of ulcers with high acidities gastrojejunostomy does not reduce the acidity to any extent. The same applies to carcinoma of the stomach, depending upon whether a gastrectomy has been done at the same time.

Gastrojejunostomy is only indicated in cases of pyloric stenosis to act mechanically to provide an outlet for food. It relieves the pain caused by the ulcer but does not reduce acidity. There is a tendency too for the formation of gastrojejunal or jejunal ulcers after gastrojejunostomy in cases with high acidity. Medical treatment will be required in all cases when a gastrojejunostomy has been performed to reduce high acidity and to prevent gastrojejunal ulcers. Gastrojejunostomy in pyloric and duodenal ulcers apparently does not relieve the pylorospasm.

Diet and Tissue Growth.—Theodore S. Moise and Arthur H. Smith (*Journal of Experimental Medicine,* July 1924) have investigated the effect of various adequate diets on the reparative process in the liver, using a normal balanced diet, a high fat diet, a high carbohydrate diet, and a high protein diet. The albino rat was used, and the tissue damage produced by choloroform injected subcutaneously, the liver being chosen as a tissue in which a fairly standard injury can be produced. The toxicity of chloroform varies with the diet in the following order of decreasing susceptibility: high fat > standard > high carbohydrate > high protein diet. The reparative process is most active on the standard balanced diet, and there is a complete return of the liver to the normal anatomical picture without evidence of scarring. On the high fat diet the reparative process is definitely delayed in comparison with the others. There are only slight differences between the high carbohydrate and high protein diets which suggest but do not conclusively show a more rapid repair with the latter diet.

Recent Advances in the Treatment of Sprue: Calcium and Parathyroid.—H. Harold Scott (*British Medical Journal,* August 23, 1924) reports that with the administration of calcium lactate and its regulation by parathyroid the disappearance of symptoms occurs early, the ionic calcium returns rapidly to normal, ordinary diet can be resumed in a shorter time, and the beneficial effects are generally steady and permanent. The treatment must not be dispensed with directly the symptoms clear and the condition of things requires to be stabilized, and the drugs must be reduced gradually with a view to seeing that the patient is able to carry on the processes unaided before all support is removed. As a rule a full diet provides all the calcium needed, and the element can be first left off, the regulator—parathyroid—being continued in full doses for another week or so. This is then reduced, and as a rule, can be stopped in its turn a week or fortnight later. If the calcium is given in full doses, but the parathyroid in only half the usual quantity, the improvement is marked, but a little slower as compared with those treated with the full dosage.

Value of the Banana in the Treatment of Celiac Disease.—According to Sidney V. Haas (*American Journal of Diseases of Children,* October, 1924) the treatment of celiac disease may be divided into two parts: 1. Keeping the intestinal tract as free from toxic accumulations as possible, which is best accomplished by a full dose (fifteen gm.) of castor oil once each week, and irrigation of the colon daily with as many liters of bicarbonate solution (fifteen gm. to a litre of warm water) as may be necessary to obtain a clear return. 2. Dietetic. Plain milk should not be given; the most satisfactory substitute is protein (albumin) milk, of which there are several varieties available, such as protein milk prepared with calcium caseinate, lactic acid milk, dry (fat free) milk, unsweetened and rarely sweetened condensed milk, and pot cheese. In addition, broths, white of eggs, gelatin, and, finally, meat may be given. Carbohydrates should be vigorously avoided except as they occur in the before mentioned milk products. Saccharin should be used for all sweetening. There is one exception, namely, sucrose as it occurs in the very ripe banana. This is tolerated perfectly, and herein lies the crux of the matter.

Banana rapidly changes the entire picture of the disease to one of well being. An underripe banana is a starch, an overripe banana is a sucrose with an invert sugar, and like most sugars easily tolerated. A ripe banana usually has a brown skin, or brown mottling. It must have a bland, sweet taste, not acrid, and should never pucker the mouth. The number of bananas offered to a child may be quickly increased by one or two daily until the patient's demand for carbohydrates is satisfied. In one case a rapid increase in the number of bananas was made, so that an infant, aged twenty-four months, took sixteen bananas daily, a short time after they were prescribed. The maximum that a child will take is usually from four to eight daily.

Fats should be avoided as carefully as carbohydrates. They are exceedingly harmful, except as they occur in protein milk and pot cheese. Codliver oil is no exception. When improvement has taken place, butter may be tried. Vegetables may be added early but carefully. The caloried requirement is from two to three times the normal, approximately one hundred calories a pound being required in the early stages of treatment.

Best Surgical Treatment of Gastric and Duodenal Ulcers.—Hans Finsterer (*Wiener klinische Wochenschrift,* July 17, 1924) emphasizes the great advantages of the extensive resection of the stomach for duodenal ulcer in order to avoid the development of a peptic ulcer, which actually did not occur in three hundred of his patients operated upon. Resection of the antrum of the stomach is not sufficient to prevent the hyperacidity permanently and to produce anacidity. The symptoms of the socalled small stomach last only a short time and then disappear, provided there are no adhesions to the efferent coil of the jejunum to retard the emptying of the stomach, and provided the anastomotic opening is large enough, admitting at least three fingers. Gastrogenic diarrheas occur, according to the author's experience, only transiently after dietetic errors. Haberer's improved anastomosis of the Billroth I method can become the method of choice only when the permanent results are decidedly better than with previous procedures (extensive resection and end to side anastomosis). At the present time the immediate dangers of the operation (greater mortality as a result of the insufficiency of the suture) are still too great.

Chronic Duodenal and Gastric Ulcer.—C. H. Peck (*Annals of Surgery,* July, 1924) states that surgical treatment of duodenal ulcer should not be resorted to until medical treatment has failed to effect a cure and it is evident that the case is chronic. The operation of choice is a simple gastroenterostomy without pyloric exclusion. In effecting the operation painstaking apposition of redundant mucous membrane edges safeguards appreciably against postoperative hemorrhage. To this end the running mattress stitch type of suture should be avoided, and a simple continuous whipover stitch used, care being taken to see that every stitch includes all layers of the stomach and gut walls, the mucous membrane of both being purposely left redundant. If spacing is accurate and tension constantly maintained postoperative hemorrhage will not occur. A lasting clinical cure may be expected in at least eighty to ninety per cent of cases treated by simple gastroenterostomy.

Splenectomy.—Ralph C. Larrabee (*American Journal of the Medical Sciences,* July, 1924) says that splenectomy ought never to be decided upon hastily. A delay of several months is generally advisable. Otherwise one may find out too late that he has mistaken leucemia in an aleucemic stage for Banti's disease, or polycythemia for hemolytic jaundice. Even if the patient is quite sick and in a stage of advanced anemia, a transfusion or two and a few abdominal taps will tide him along and perhaps lead to a degree of temporary improvement that will greatly increase the chance of success, beside giving opportunity for study. Reasonable delay will rarely injure the patient's chances and time is a great diagnostician.

Influence of Diet Upon the Liver Injury Produced by Carbon Tetrachloride.—Nelson C. Davis (*Journal of Medical Research,* September, 1924) demonstrated by experiments with dogs in which liver injury was produced by carbon tetrachloride that an all fat diet not only does not protect against injury, but is more likely to induce a maximum of liver injury than is a short period of starvation. Long periods of fasting (judging from analogy with choloroform) are likely to be a dangerous preparation for tetrachloride administration. On the other hand, a few days of liberal mixed, or high protein, or high carbohydrate diets, are more or less protection against injury. Factors of diet therefore exert an enormous influence upon the toxicity of carbon tetrachloride.

Rôle of Anhydremia and the Nature of the Toxin in Intestinal Obstruction.—Thorsten Ingvaldsen, Allen O. Whipple, Louis Bauman, and Beverly C. Smith (*Journal of Experimental Medicine,* January, 1924) report work on the water loss, chemistry of the blood, and nature of the toxin produced in the obstructed small intestine of dogs. There may occur a moderate loss of water, especially in high obstruction, but it is an inconstant phenomenon apparently not related to the severity of the symptoms. An increase in the urea and nonprotein nitrogen occurred in all instances, but with few exceptions the elevation was slight and apparently proportional to the severity of the symptoms. There was a marked decrease of the blood chloride in nearly every intance, apparently related to the frequency of vomiting. A discussion of the chemistry of the toxin found is included.

Studies on the Total Bile.—Philip D. McMaster (*Journal of Experimental Medicine,* July, 1924) states that when a diet rich in cholesterol is given, the amount of the substance in the bile greatly increases. The concentration of the substance per c. c. in almost every instance was greater. In the fasting dog, the cholesterol yield was greatly cut down, and the concentration of the substance per c. c. greatly increased. The cholesterol quantity and concentration in dog bile are evidently subject to profound modification by dietary influences. The changes are not slight and inconstant as the literature would lead one to expect. The cholesterol yield of the bile does not parallel that of bilirubin.

Radium Therapy in Cancer of the Esophagus.—William Hill (*Journal of Laryngology and Otology,* February, 1925) thus sums up his results. In about one third of the cases there was remarkable improvement, in another third there was very substantial improvement, and in the remaining third the improvement was either very slight and fleeting, or there was either no improvement at all, or the patient was rather worse than before. In three cases the procedure was followed by fatal results within a few days of the application.

Hematemesis Without Lesions.—Gustave Monod (*British Medical Journal,* April 12, 1924) reports three cases in which gastric or duodenal ulcer was diagnosed but not found at operation. Two cases showed oozing from probable microscopic lesions. The third case showed bleeding from congestion as a result of duodenal stenosis. The following theories are advanced to account for the hemorrhage: disturbance of the normal reaction of the general nervous system on the visceral system; irritation of the sympathetic vasomotor centres in the tractus intermediolateralis of the medulla, or of the nerve ganglions or nerve endings, and hepatism.

Treatment of Diffuse Peritonitis.—H. P. Marshall (*Northwest Medicine,* March, 1925) says that in diffuse peritonitis the originating focus must be removed; the abdomen must be flushed out without manipulation, sponging or suction; the intraintestinal toxemia should be intelligently treated; dehydration must be prevented; acidosis should be combated; starvation should be minimized; and all complications diagnosed early and appropriately treated.

Relation of Gallbladder to Development of Jaundice Following Obstruction of Common Bile Duct.—Frank C. Mann and Jesse L. Bollman (*Journal of Laboratory and Clinical Medicine,* April, 1925) state that following ligation of the common bile duct, signs of icyerus, that is, bile pigment in the urine, plasma, sclerotics and mucous membranes, do not develop for from thirty-six to forty-eight hours after operation. If the gallbladder is removed when the common duct is ligated, the urine and plasma contain definite amounts of bile pigment within three to six hours after operation, and the sclerotics and mucous membranes are definitely yellow within twenty-four hours. The difference in the rate of accumulation of bile pigment is considered as evidence of the ability of the gallbladder to concentrate the bile secreted by the liver.

Effect of Specific Cholecystitis on Bile Concentrating Activity of Gallbladder.—Jesse L. Bollman, Frank C. Mann and Pierre DePage (*Journal of Laboratory and Clinical Medicine,* April, 1925) produced a specific cholecystitis in dogs by the intravenous injection of solutions of chlorinated soda. The time of appearance and rate of development of bile pigment in the blood and urine of these animals following ligation of the common bile duct depend on the degree of involvement of the gallbladder by this acute process. The facts reported show that the function of the gallbladder of concentrating the bile is impaired, or may be totally lost, in the presence of an acute inflammatory process in the gallbladder.

Protein in the Edible Portion of Oranges.—Arthur H. Smith (*Journal of Biological Chemistry,* February, 1925) reports in the orange juice as burred, but not the fibrous shreds, there is at most 0.2 per cent. protein, all of which is located in the highly pigmented material contained in the chromatophores of the pulp vesicles. The protein is insoluble in water, neutral salt solution, or weak acids, but is soluble in weak alkali. It is not precipitated from its solution by ninety-five per cent. alcohol, nor is it coagulable by heat at neutral, acid, or alkaline reactions.

PEDIATRICS

The Salivary Urea Index in Children.—Joseph K. Calvin and Bertha L. Isaacs (*American Journal of Diseases of Children,* January, 1925) report that their results of the investigations on the salivary urea index in children agree essentially with the work done by Hench and Aldrich more especially in adults. There is a distinct correspondence between the salivary urea index and the blood urea value. The salivary index definitely indicates the presence or absence of urea retention in the body and in the blood. Although the salivary urea index does not give absolutely accurate figures for the blood urea, a clinically approximate estimate of the blood urea is obtained in retention cases by the application of the formula.

This test is especially applicable to children because of the ease with which a specimen of saliva may be obtained. It can be used as a routine method in cases of suspected retention, or in any other cases (especially albuminurias) where the nonprotein nitrogen content is desired. If high indexes are found, denoting retention or a borderline case, further blood studies may be made. In protracted cases frequent salivary index tests may be made with occasional blood urea checks. The salivary urea index should prove a very valuable adjunct to the phenolsulphonephthalein test in the study of renal function.

A Case of Scaphocephaly With Malformations of the Skeleton and Other Tissues.—Marian C. Putnam and K. F. Pelkan (*American Journal of Diseases of Children,* January, 1925) describe a case, the chief characteristics of which together with Hurler's two cases, form a picture differing from any other clinical group: 1. Negative family history. 2. History of the development in the latter half of the first year of a pronounced kyphosis, delayed dentition, a general apathy, which in Hurler's cases amounted to a true mental retardation after the age of two years. 3. Physical examination shows in addition: short heavy bodies; heads of abnormal shapes, one oxycephalic, two scaphocephalic, with open fontanels; no evidence of increased intracranial pressure; infantile type of face with heavy jaw and broad alveolar process; marked dorsolumbar kyphosis; short heavy bones, especially arm bones and clavicles; limitations of movement at elbow and shoulder; short pudgy hands with incompletely extended fingers; pot belly (with herniæ in Hurler's cases); redundancy of superficial tissues; hypertrichosis; corneal clouding.

Feeding of the Abnormal Baby by the Socalled Truby King Methods.—Mildred M. Burgess (*Lancet,* January 17, 1925) draws the following conclusions from a review of thirty-nine cases:

1. An abnormal baby has a great intolerance for fat.

2. It is impossible to feed all abnormal babies on a percentage system if the percentages followed are those at present given for human milk.

3. It is unwise to risk the introduction or increase of fat in the food of an abnormal baby unless there has been no digestive disturbance for some considerable time, and not then if the weight curve is rising satisfactorily without it.

4. The caloric value of the food required by a marasmic baby is probably more than half as much again as its theoretical value, or, to put it another way, the same standard of feeding by caloric values cannot be applied when a baby is exceedingly below its average weight for its age even when half as much again is allowed.

5. It has not been proved that the socalled Truby King method of percentage feeding is the best and only substitute for breast milk. This is evidenced as follows: That in many infants sent out in good health, resort had to be had to breast milk to put them on the right road; that gain in weight and the general improvement, which were first obtained were lost through breakdowns during the course of the treatment, and the total gain in weight was less than would have obtained otherwise; that some babies actually suffered in consequence of the treatment.

6. The difficulty of ascertaining a baby's power of absorption is a vital point, for it may be found that a baby fed on an artificial food, as cow's milk, needs to be given a higher percentage of some of the food elements because in this form he can assimilate only a certain proportion of the whole, rejecting a great deal which is passed in the stools; whereas, in the form the elements are presented in human milk, although in lower percentages, practically the whole may be assimilated.

Significance of Lymphangitis Occurring With Cutaneous Tuberculin Tests in Children.—Frederick Eberson (*American Journal of Diseases of Children,* January, 1925) reports that the significance of lymphangitis with tuberculin reactions is to be considered from the viewpoint of an infection with tuberculosis which in children manifests itself as a glandular disease. The lymphatics are the distributors and the phenomenon of lymphangitis speaks for an active tuberculous process. A glandular reaction following an injection of tuberculin is akin to a more pronounced skin reaction and is in turn an integral part of the most pronounced reaction, lymphangitis, which results from an active sensitization of the lymph channels to the products of the tubercle bacillus.

Concentrated Feeding for Infants and Children.—By the term concentrated feeding Tobias L. Birnberg (*Archives of Pediatrics,* December, 1924) means the feeding of a large amount of food value (in either calories or nem) in a small bulk. There are many kinds of concentrated foods used in pediatrics, but the most common are: 1, Whole milk plus seventeen per cent. sugar; 2, concentrated albumen milk plus ten to twenty per cent. sugar; 3, various butter, flour, sugar mixtures; 4, pastes or thick cereals.

The indications for concentrated feeding are: 1, Vomiting; 2, anorexia and other difficulties in food intake; 3, dystrophy with loss of tolerance; 4, complementary feeding in nursing infants; 5, exudative diathesis; 6, enuresis and allied conditions; 7, in exudates without kidney involvement; 8, asthenic and undernourished children. Concentrated feeding may be of benefit in nervous vomiting, infectious vomiting and in pylorospasm. The forms of anorexia in which concentrated feedings are valuable are: 1, Nervous anorexia; 2, anorexia accompanying acute and chronic infections, especially tuberculosis; 3, anorexia in premature babies; 4, anorexia due to mechanical and inflammatory conditions in the pharynx, as severe tonsillitis, during intubation or pharyngeal abscess where this is due to pain, both a lack of desire and difficulty in swallowing.

The contraindications for concentrated feeding are few, the main ones being: 1, hot weather; 2, dystrophy where the tolerance is unknown and possibly low; 3, among ignorant people where the patient cannot be kept under observation.

Cutaneous Reaction in Allergic Diseases of Infancy and Childhood.—W. Ray Shannon (*Archives of Pediatrics,* December, 1924) states that it is contended that in the interpretation of the cutaneous protein test in infancy and childhood, an erythema must be considered as the indication of a positive sensitization. Five striking cases are cited, in which no results would have been possible had not such an interpretation been made. Further support for this contention is found in the fact that an erythema may frequently be demonstrated to precede a wheal type of reaction in an increasing sensitization, and in that it may also often be shown to follow a wheal in a decreasing sensitization. It is common for the tissues of the allergic individual to react to irritative phenomena in a magnified manner. As a result, it is not uncommon to find some erythema persisting around all of the tests. This does not disprove the original contention, as satisfactory clinical results can frequently be obtained with therapy based upon the most marked reactions. It does, however, demonstrate as fact, that the interpretation of the positive reaction is a relative thing, dependent upon the particular reactivity of the tissues of the particular individual concerned at the particular time.

Fat Absorption in Infants.—Richard C. Tefft (*Boston Medical and Surgical Journal,* May 21, 1925), in an effort to determine accurately the reaction of a human infant to large amounts of fat in the diet, his ability to utilize large amounts of fat, the reaction of varying amounts of fat in the diet on calcium absorption, of calcium on fat absorption and of both on the phosphorus absorption, placed a four months old infant on a metabolism frame and fed very carefully controlled and analyzed diets containing varying amounts of fat and calcium. Accurate determinations of the neutral fat, fatty acid, soap and calcium were made on the stools and daily determinations of the phosphorus excreted in the urine.

The amount of fat excreted, almost entirely in the form of soap, the amount of neutral fat being at all times negligi-

ble, increased steadily as the amount of fat in the diet increased, but the proportion of fat excreted to the fat intake remained approximately constant at about 10 per cent. indicating that 90 per cent. of the fat taken in the diet was absorbed. When the calcium in the diet was very markedly increased these proportions changed to 15 per cent. excreted and eighty-five per cent absorbed. The phosphorus excretion in the urine rose steadily with increase in the fat intake until the patient was on a milk mixture containing about four per cent. fat, after which it remained about constant despite increases in the fat. On this diet fifty-five per cent. of the calcium in the stools was excreted in the form of soap. With marked increases in the amount of calcium in the diet the excretion of phosphorus in the urine decreased rapidly, falling practically to zero on a diet consisting of fat milk with approximately twenty gm. of calcium lactate added daily. Throughout the course of the experiment the calcium excretion in the stools was roughly fifty per cent. of the intake, indicating the probability that an equal amount of calcium was absorbed. This held when the calcium intake was varied from 0.88 gm. of calcium per day to 3.41 gm of calcium a day. The only gastrointestinal disturbance in the course of the experiment was a diarrhea occurring during one of the fat free periods. Throughout the experiment the baby gained at a rate somewhat greater than the average for hospital babies of this age.

Biliary Affections Beginning in Infancy from the Clinical and Constitutional Pathological Viewpoint.—Hans Abels (*Wiener klinische Wochenschrift,* December 18, 1924) states that the socalled biliary colics are frequently due to biliary affections beginning in early childhood, which are recognized only later in life. Girls are affected more frequently than boys. The symptoms are of a functional nature, and are not due to cholelithiasis, but a neurosis of hypermobility.

These children are frequently subjected to appendectomy, after which they remain free from symptoms for a time, but the symptoms eventually return. There is a distinct evidence of a hereditary factor. In addition, these children show a predisposition to all sorts of infections, such as otitis media and, particularly, suppurative diseases of the urinary tract (cystopyelitis). A diminished appetite, constipation and intestinal fermentation are frequently observed. The lower part of the gallbladder is tender and there is a marked defense reaction (rigidity) of the right rectus muscle. Generally, Boas' point to the right of the tenth and eleventh dorsal spinous processes is tender, and the liver is enlarged.

Suitable prophylactic measures are an important part of the treatment. In light cases antispasmodics are sufficient. Psychotherapy is only of transient value. The most important part of the treatment consists in the avoidance of obstipation and intestinal fermentation, and repeated courses of Karlsbad water together with a very strict diet.

Diabetes Mellitus in Childhood and Insulin Treatment.—Richard Wagner (*Monatsschrift für Kinderheilkunde,* January-February, 1925) draws the following conclusions:

1. In light cases, in which the sugar can be reduced dietetically with an amount of carbohydrate that can reduce the acidosis, it is occasionally desirable to give transient treatment with insulin. In such cases the tolerance is rapidly increased with a purely dietetic treatment.

2. For the rapid reduction of sugar and the improvement of the state of nutrition it is occasionally desirable to give transient insulin treatment also in light cases of diabetes. Simultaneous insulin therapy in small doses makes the dietetic treatment easier and may avoid starvation days.

3. In severe cases, underweight, and showing severe retardation in growth, insulin therapy is absolutely indicated, just as in coma.

4. After the child has reached the proper state of nutrition for that particular age, it would be a mistake to force additional weight, and, furthermore, with a slow reduction in diet the previous amount of insulin used should be maintained and then should be reduced only slowly and steplike.

5. The level of the fasting blood sugar content is a better criterion of the severity of the diabetes than the sugar excretion.

6. In the severe cases of diabetes observed, the amount of the insulin had to be doubled during the course of three to four months in order to obtain the same effect.

7. Consequently a permanent increase in tolerance cannot be achieved with insulin in severe cases of diabetes.

8. Even in apparently light cases the increase in tolerance obtained with insulin is only transient.

9. In cases with a high blood sugar content in the precomatous state, the administration of insulin and of fluids is sufficient without a simultaneous administration of sugar. Only when the blood sugar level has fallen below 0.2 per cent. is the simultaneous administration of glucose necessary and advantageous. The equal distribution of the insulin throughout the day and the continuation of the treatment during the night is important.

10. The effect of insulin is essentially a primary effect on carbohydrate metabolism. The inhibition of diuresis and the reduction of the acidosis are secondary effects of the insulin, standing in close association with the evaluation of the carbohydrate. Insulin therapy is a true substitution therapy.

11. In two children, aged three and a half and five years, respectively, there suddenly developed an especially severe diabetes with precomatous symptoms in connection with an ill defined febrile disease and a catarrhal icterus. In these cases particularly the diabetic process was markedly improved after a short course of insulin therapy, so that the insulin therapy could be interrupted. The author considers these conditions as acute states of exhaustion of the island apparatus, which can be markedly improved.

12. In the alimentary intoxication of infants, insulin therapy may be a life saver together with the intravenous administration of glucose.

Pulmonary Tuberculosis in Childhood.—F. G. Chandler and T. W. Preston (*British Journal of Children's Diseases,* January-March, 1925) emphasize the importance of the early recognition of tuberculosis in childhood. In many cases a certain diagnosis is exceedingly difficult, and not infrequently impossible, but the following symptoms and signs are of great help.

First and foremost of these symptoms is a barking, dry, paroxysmal cough at night—often described by mothers as a croupy cough; then vague ill health; fever, especially evening fever, nightsweats, loss of weight, or failure to gain weight.

Of the signs, there may be parasternal or paravertebral dullness; Krönig's bands may be narrowed. Whispering resonance may be heard loudly over the dorsal spines down to the fourth, fifth, or sixth dorsal spine, or even lower. This is the socalled D'Espine's sign, which the authors regard as of value, though, like the other signs, not absolutely pathognomonic of enlarged bronchial glands. Furthermore, even though the glands may be enlarged, they need not necessarily be tuberculous. There may be functional systolic murmurs, but these are of little help in diagnosis. There may be a retraction of the lower lung border, so that there appears to be impaired resonance over one base. Constant râles may appear in any part of the chest. There may be the earliest stage of clubbing of the fingers. For the more gross and obvious signs there may be evidence of a small pleural effusion, or when the lungs are definitely infected there may be the classical signs of dullness, crackling rales and altered breath sounds.

Other forms of chronic infection or toxemia must of course first be excluded: for example, Bacillus coli infection of the urinary tract, infected tonsils and adenoids, otitis media; and one must bear in mind the possibility of a foreign body in the bronchus, and nontuberculous fibrosis, postpneumonic conditions, bronchiectasis and tuberculous glands in other parts.

The symptoms and physical signs having been carefully considered, the following investigations must be made: 1, temperature record; 2, weight record; 3, sputum examination; 4, feces examination for tubercle bacilli; and 5, roentgenography of the chest. A tendency to stigmatize all hilum shadows and striations as pathological and as tuberculous must be avoided.

Pulmonary tuberculosis does occur in infants and childhood, and is not extremely rare. It may run a long, chronic course. It is not necessarily fatal. The earlier stages should be looked for carefully, and for this further diagnostic methods of precision are needed. While it is obviously undesirable to stigmatize every feeble child as tuberculous, it must not be forgotten that thoracic tuberculosis is indoubtedly responsible for much chronic illness in infancy and childhood. The stronghold of the disease is the bifurcation and bronchial glands, and it is probable that from these the lungs are infected or reinfected.

Medicolegal Notes.

ENTREPRENANT TO COMMIT CRIME UNDER HARRISON ACT NOT PROVED

In a prosecution for dealing in narcotic drugs without being registered, the evidence tended to show that the government inspector, having some reason to believe that morphine and other narcotics were being sold to addicts, and that the drugs were obtained in a certain drug store, sent to this place of business an individual who asked the clerk for a "shot" to be administered presently; later he came back with some marked bills and obtained a large quantity from the defendant, an employee in the drug store, but not a prescription clerk. The Circuit Court of Appeals, Seventh Circuit, held, Bethea v. United States, 1 Fed (2nd) 290, that this evidence did not support the contention that the defendant was entrapped, or was led into the commission of the crime by the government's officer.

In such a case, the court held, it is not necessary for the government to show that morphine hydrochloride is a derivative of opium.

An employee in a drug store, who sells a customer narcotic drugs, the evidence showing that he was not acting within the scope of his employment, was held to be a person who sells or deals in such drugs within Section 1 of the Harrison Act, and must be registered thereunder.

PRACTISING WITHOUT A LICENSE

The Illinois Supreme Court holds People v. Walder, 148 N. E. 287, that the Illinois Medical Practice Act of 1923 "recognizes the different methods of treating human ailments, and prescribes reasonable and uniform regulations for testing the qualifications of persons who desire to practise medicine in all its branches, and of persons who desire to practise some limited form of treating human ailments. This act meets the constitutional objections which rendered void the earlier medical practise acts, and is valid legislation."

The defendant in proceedings for violation of the act by practising chiropractic without a license contended that the act was unconstitutional; first, because "the practise of chiropractic is a useful and harmless calling, which cannot be regulated by the state." The court rejected this contention, and said: "Any method of treating human ailments which, when practised skillfully, can restore a diseased human body to health is capable of doing great harm when practised without care or skill. A method of treating human ailments cannot be both useful and harmless. If it is sufficiently efficacious to be useful, it is at the same time capable of producing harmful results."

The requirement of section 5 requiring the elapse of twenty-two months between the time the student begins his eighteen months' course of study, divided into three six month terms, is held not to be so arbitrary or unreasonable as to be unconstitutional. The court said: "Whatever method of treating human ailments is used by a physician, he should be able to detect readily the presence of disease and prescribe appropriate remedies for its removal. Taking into consideration the subject matter with which the Legislature was dealing, we are of the opinion that the requirements applicable to the limited practitioner are not subject to the charge of being arbitrary or unreasonable, but that they are liberal when compared with the requirements of the same act applicable to persons who desire to practise medicine in all of its branches."

Section 13, providing for the issue of license without examination to graduates of recognized colleges who have passed examinations for admission to the medical corps of the army, navy and public health service of the United States, is held not discriminatory.

HOSPITAL RECORDS AS EVIDENCE

The Illinois Supreme Court holds, Kimber v. Kimber, 148 N. E. 293, that hospital records are admissible in evidence on the same basis as books of accounts, and before they can be admitted in evidence all persons who make the entries are required to testify to their correctness.

ROAD GRADER'S DEATH FROM LIGHTNING HELD COMPENSABLE

The New York Court of Appeals, Rung v. New York, 144 N. E. 889, on the authority of Matter of Madura, 238 N. Y. 214, 144 N. E., 505, affirming 207 App. Div. 879, 201 N. Y. Supp. 942, affirming an award under the Workmen's Compensation Act for the death of a foreman of laborers in the employ of the city of New York, who, while employed in grading a road, sought shelter from a storm under a tree and was struck by lightning and killed.

PNEUMONIA FROM SUCCESSIVE WETTINGS NOT COMPENSABLE

The Texas Commission of Appeals holds, Texas Employer's Ins. Assn. v. Jackson, 265 S. W. 1027, that successive wettings of an employee by rain, resulting in a cold and pneumonia, were not compensable as injuries or personal injuries sustained in the course of employment under the Workmen's Compensation Act, not falling within the definition in the statute of such injuries as "damage or harm to the physical structure of the body and such diseases or infection as naturally result therefrom."

BURNS, ETC., CAUSED BY SODA ASH HELD COMPENSABLE

The Oklahoma Supreme Court holds, Ward v. Beatrice Creamery Co., 230 Pacific 872, that the term "accidental injury" as used in the Workmen's Compensation Act, is to be broadly and liberally construed so as to entitle to compensation where the injury results through some accidental means, was unexpected and undesigned, or may be the result of some mischance or of miscalculation as to the extent of voluntary action.

Burns, scalds, and salivation suffered by an employee, caused by the use of a substance known as soda ash in the process of sweetening cream, in a hot room in a creamery in the course of claimant's employment, were held to be within the operation of the act, the granting of damage for which was within the exclusive jurisdiction of the State Industrial Commission.

Letters to the Editor.

ANTISEPTIC PROPERTIES OF INSECTS

CHICAGO, 1925.

To the Editor:

In the *Journal of the American Medical Association,* for June 13, 1925, is an article on stitching wounds with the mandibles of ants and beetles. I refer to the same practice in my essay on "Surgery Among Uncivilized Races" which appeared in the MEDICAL JOURNAL AND RECORD, July 16, 1921. Moreover, I speculated as to whether the formic acid had any antiseptic properties.

Thoracic Pain*

Its Relation to Visceral and Spinal Disease

GEORGE SWETLOW, M.D.

New York

Pain is an adaptation serving to remove noxious irritants, which tend to injure the organism. The discomfort elicited may vary in degree from a sensation of soreness, aching, or dysesthesia to that of intense agony. Under all circumstances it is abnormal, calling the attention of the body to an existing disorder.

All pain is affective in nature. The thalami are the structures which all affective stimuli finally reach. The cerebral cortex, through the corticothalamic fibres, inhibits the thalamic impulses from exerting uncontrolled reactions over the organism. If, however, there is present an extreme state of psychical tension or instability, the cortical supervision over the thalami is diminished and, as a result, there is a release of the thalamic control. This will explain the increased pain reaction of the nervous and excitable, the worried and chronically ill.

Pain varies greatly in intensity and may be described as burning, darting, lancinating, cutting, tearing and throbbing. It may be diffuse, localized, or may radiate along a nerve trunk. The pain may run completely or partially around the body and is then designated as a girdle pain. It may be felt in an area which, on stimulation, is anesthetic. This phenomenon is known as anesthesia dolorosa. Some neuritic pains are increased by pressure while others are diminished thereby, as in lead colic. Milder grades of pain phenomena are the dysesthesiae, which manifest themselves as sensations of numbness, tingling, formication, heat, cold, heaviness, and even tired feeling.

Chest pains may be classified according to their method of production in the following manner. First, those that are due to disease in the thoracic or abdominal viscera and are referred to the chest wall, e. g., coronary disease, aortic aneurysm, splenic disease, gastric and duodenal ulcer. Second, those that are produced by disease in the spinal meninges about the spinal roots. These may be due to an extramedullary new growth as extramedullary sarcoma, or to an intramedullary neoplasm with extension to the spinal roots, e. g., intramedullary gliosis. Infectious diseases like tabes dorsalis and ascending infectious meningomyelitis also involve the spinal meninges. A degenerative spinal cord disease like multiple sclerosis may also extend to the spinal meninges. Third, those processes that involve the bony vertebrae either by pressure erosion as mediastinal lymphosarcoma and Hodgkin's disease, or by tumor formation in the vertebrae themselves as carcinomata and sarcomata or by infectious processes as spondylitis deformans, tuberculous caries and suppurative infections. The pains produced by most of these diseases will be discussed briefly and illustrative cases presented.

The pains which are felt in the chest wall and whose cause is at a distance are known as referred pains. There are just a few facts necessary for a fair comprehension of this phenomenon. The areas to which pain will be referred as well as the hyperesthesia elicited can be understood by knowing the nerve supply of an organ. Let us cite a few examples. The spleen is supplied by the third to the tenth thoracic nerves. A disease in the spleen, as an infarct or a perisplenitis, will encroach upon endings of the afferent sympathetic fibres. The pain impulses will be carried by the axones to certain of the cells in the posterior spinal ganglia of these thoracic nerves. Here the impulses will pass into the spinal cord giving the organism a sensation of pain in the dermatomes supplied by the posterior ganglia stimulated. As a result pain is complained of in the skin areas supplied by the third to the tenth thoracic nerves. Thus any of the abdominal and thoracic viscera which are in connection with the thoracic segments may refer pain to the chest wall. This irritation reveals itself in a peculiar manner. The pain occurs spontaneously and is rarely augmented by deep pressure. There is a hyperesthesia of the skin and at times an unpleasant sense of discomfort is produced on light stroking.

More and more frequently our attention is being called to an apparently insignificant intercostal neuritis only to find ourselves later confronted by all of the dreaded symptoms of a spinal cord neoplasm. At times it is entirely too late for surgical cure or even relief. Tumors of the cord are either extra or intramedullary in location. The extramedullary tumors are either hard or soft. The former are typified by fibromata and the latter by lipomata. The

most common seat of attachment is about the dorsal roots. Owing to the fact that the roots are enveloped by the meninges, pain is produced when the roots are impinged upon. The pain has all the attributes of a root pain. This root pain usually appears early, is lancinating in character and is situated in an intercostal space. Herpes zoster may be present due to the irritation of the posterior ganglion cells. The pain is usually unilateral. A unilateral pain which becomes bilateral is practically always pathognomonic of a meningeal neoplasm, indicating a sweeping around of the tumor to the opposite side. At times instead of a lancinating pain, paresthesiae of various shades are elicited at the level of the root which is impinged upon. The hyperesthesia later gives way to a hypesthesia or even anesthesia as the root becomes destroyed. There is early a diminution or loss of the epicritic or protopathic sensibility in the involved root area. Often it is observed that severe pain along the distribution of a root will be complained of although the same is anesthetic to even intense stimulation. This phenomenon is known as anesthesia dolorosa. The nerve trunk is not sensitive to pressure.

Case I.—N. S., male, aged forty-seven years. Five months before his admission to the hospital the patient complained of sharp knifelike pains at the level of the xiphoid cartilage which radiated to the right chest both anteriorly and posteriorly. The pain was steady in character being markedly aggravated during the night or upon lying down. He was treated for pleurisy. Some time after the appearance of this pain his lower extremities became weak and unsteady. In a short time they became completely paralyzed. A diagnosis of spondylitis was made. At this period he was admitted to the Montefiore Hospital. Here he presented a level of hyperesthesia along the distribution of the seventh dorsal segment together with signs of a transverse lesion of the cord. On operation an extradural neoplasm was found extending from the third to the seventh dorsal segments. Microscopic examination showed the tumor to be a sarcoendothelioma. Locomotion reappeared on the removal of the neoplasm.

A root pain must be differentiated from that which is known as a neuralgic pain. In an intercostal neuralgia the pain is along the course of the nerve, being sharp and knifelike in character. There are three points in the course of the nerve which are tender spots and correspond to the points where the branches of the spinal nerves make their exits. One area of tenderness is near the vertebral spinous process and is at a spot where the posterior primary branch of the nerve appears. Another area is in the midaxillary region, where the lateral cutaneous nerve is found. The third point is at the costosternal junction where the anterior cutaneous nerve emerges. The corresponding vertebra is at times tender on percussion. Movements particularly increase the pain. A unilateral intercostal neuralgia should always excite a lively suspicion that we might be dealing with a spinal cord neoplasm, tabes dorsalis, spinal caries, or aneurysm.

Intramedullary neoplasms have often been mistaken for extramedullary ones. Often it is found to the chagrin of all concerned that on operation no extramedullary new growth is present. On examination of the cord a uniformly enlarged non-removable lesion is seen. The cause for this confusion hinges on the fact that as soon as the intramedullary process extends to about one eighth of an inch from the entrance of the dorsal roots, a root pain is produced with a level of hyperesthesia. It is important to note that there is another form of pain known as tract pain. The sensation is that of freezing or that of soft wind passing over the skin. An important fact in the differentiation of an intramedullary neoplasm from that of an extramedullary new growth is that the former gives sensory disturbances first and later motor, while the latter gives motor first in the form of weakness and sensory disturbances last.

Case II.—J. W., male, aged fifty-seven. Patient's illness began six years before admission with an intense tearing pain in the left supraclavicular area. Three months later his right upper and lower extremities became distinctly weak and sharp sticking pains appeared in the lower thorax. At times the pain was tearing in character, while at others it was constricting in nature. Several weeks later his left lower extremity weakened. At present he complains of severe tearing pains over the entire left chest. Occasionally they are viselike in type. Physical examination shows an atrophy of the shoulder girdle with fibrillary twitching. The upper and lower extremities show pyramidal tract signs. Pain and temperature sensibilities are lost over the entire right arm, right anterior chest, part of the left upper chest and below the knees. The vibratory sense is lost over the entire body. The onset of the disease with the typical root pain, the involvement of vibration, pain and temperature sensibilities and pyramidal tract signs pointed to an extramedullary neoplasm. However, the duration of the disease with slight progression and the peculiar involvement of the pain and temperature sense point to a syringomyelia with a localized serous meningitis about the roots.

There are two important pathological entities which produce their clinical picture by inflammatory processes upon the nerve roots. I refer to such entities as ascending infectious meningomyelitis and tabes dorsalis. It has been observed time and again that in patients suffering from abscesses, bed sores and pelvic cellulitis, may, after a period of time there develop severe root pains. These root pains correspond to the segments of the cord which supply the affected area. Often these pains and levels of hyperesthesiæ are higher than the root segments supplying the infected area. Orr and Row investigated this problem. They injected bacteria into a nerve. Within twenty-four hours the organisms had accumulated in the lymph spaces which are found on the internal surface of the perineurium. As the organisms passed up the lymph spaces of the spinal nerves and reached a point where the posterior roots became naked, losing their neurolemma sheaths, a degeneration of the posterior roots and the ganglia was produced. The dura about these roots showed a marked inflammatory reaction. These lymph spaces are continuous with those of the pia-arachnoid and with that of the cord itself. The infection passing into the pia-arachnoid spaces proceeds up to higher levels and implicates as a result many

roots far above the root segment first attacked. This mode of extension accounts for the fact that there are in an ascending infectious meningomyelitis several areas of root pains and levels of hyperesthesiæ. The distress produced has the characteristics of root irritation.

Case III.—J. S., female, aged thirty years. Several days following the incision of an infected Bartholin cyst, the patient complained of intense pain localized in the lumbar region. A diagnosis of nephrolithiasis was made. Two weeks later severe knifelike pains appeared in the epigastrium which radiated along the anterior inferior costal borders of the thorax. At the same time she complained of intense pain in the right shoulder. A diagnosis of cholelithiasis was considered. Five days following this attack her lower extremities suddenly became paralyzed. Physical examination showed a spastic paraplegia with severe zones of hyperalgesia over the thorax. A laminectomy was performed on the third to the fifth thoracic vertebrae. Approximately half an ounce of free pus was found exuding up from the spinal canal. The dura was necrosed and the cord and roots were grayish in appearance.

No discussion of pain would be complete with the omission of that produced by tabes dorsalis. The dorsal roots before entering the cord are made up of two groups of fibres. One group is of fine calibre and goes to form the tract of Lissauer. The other group is coarse in character, entering mesially to the dorsal gray horn, and goes to form the Column of Goll and Burdach. Just after entering the cord these axones lose their sheaths of neurolemma. It is here that early cases show the first signs of degeneration. As the pathological process extends, changes in the dorsal roots and in the spinal ganglion cells appear. An inflammatory reaction ensues at the point where the roots enter the cord and lose their neurolemma and a leptomeningitis is produced. As a result of this root involvement pain is caused. The characteristic pain is described as lightning in character. It is one of the earliest manifestations of the disease and often precedes any of the other symptoms by years. It is recognized by the severity and the suddenness of the onset and the lightning rapidity of each separate pain. The pains take the course of root distribution and not that of the nerve. They are short and sharp, striking here and there. The paroxysms may last from ten minutes to twenty-four hours. A pain that persists longer than thirty-six hours is not a common occurrence. It should make one cautious and to consider other causes. The nerve trunks may be painful to pressure during the attack. However, pain sensibility is lost over the nerve on deep pressure later in the course of the disease. Often the lightning pains subside and one boring in nature supervenes. At times these pains are preceded by various paresthesiæ. One case at the hospital complained of tingling and a persistent crawling sensation over the chest wall.

Case IV.—J. B., male, aged forty-two. Two years before admission to the hospital he complained of severe knifelike pains over the anterior and posterior aspects of the thorax. At the same time he experienced sharp shooting pains over both of his lower extremities. These pains appeared during various intervals. Two years after the onset of these pains his gait for the first time became unsteady. Walking in the dark became impossible. Physical examination showed many root levels of hyperalgesia over the chest and lower extremities. All of the classical signs of tabes dorsalis were observed, i. e., staggering gait, positive Romberg, Argyll-Robertson pupils, absence of both the knee and ankle tendon reflexes, delay of the conduction time of pain stimulation.

The neurologist now and then is confronted with thoracic pain produced by multiple sclerosis. Although this is not frequent, it is none the less important—for often this root pain is confusing and leads to unnecessary operative interference. In fact, many cases have been operated upon for a mistaken diagnosis of extramedullary cord tumor. Nonne mentions these thoracic pains in multiple sclerosis and several have been seen in the Neurological Wards of Montefiore Hospital. Recently, a careful pathological study of the roots in such a case was made by Dr. Hassin. He found that the pia-arachnoid was thickened and infiltrated. The thickening was closely associated with a hyperplasia of the mesothelial and connective tissue cells. The infiltration consisted of lymphocytes, plasma cells, polyblasts, fibroblasts and mesothelial cells. The cellular elements and their fragments were freely scattered in the meshes of the pia-arachnoid and in some instances were so densely gathered that the affected region resembled a meningitis. There results clinically a root pain and a level of hyperesthesia. However, the presence of multiplicity of lesions, a history of remissions and exacerbations, the irregularity of the involvement, the loss of the abdominal reflexes, the presence of a bilateral optic temporal pallor, and the triad of Charcot, i. e., scanning speech, nystagmus, intention tremor, should cause a careful investigation of the pain before entertaining a diagnosis of a new growth about the spinal cord.

Case V.—S. F., female, aged thirty-eight. The patient's illness began approximately ten years before admission. She complained of sensations of pins and needles about the lower chest and abdomen, burning pain and itching over the neck and upper back. Six months later her lower extremities felt heavy, the gait became shuffling, the limbs spastic and a viselike compression about the chest appeared. The pains in the back were at times knifelike and at others aching in nature. Physical examination showed most of the signs and symptoms of multiple sclerosis. On operation, the dura was incised and a considerable amount of cerebral spinal fluid escaped. The cord was markedly congested and the veins were dilated and tortuous. The arachnoid was cloudy. No spinal cord tumor was found and an operative diagnosis of a localized meningomyelitis was made.

Many of the ailments that produce thoracic pain are localized in the chest cavity. I refer particularly to such diseases as mediastinal lymphosarcoma and Hodgkin's disease. A mediastinal new growth may reveal itself by a localized pain. The location depends upon the site of the neoplasm. Tumors in the anterior mediastinum generate substernal pain. New growths in the posterior mediastinum initiate pain in the back by causing erosions through the

vertebræ. Masses on either side of the mediastinum cause pains which radiate along the sides of the thorax. They may be sharp and continuous, intermittent, or paroxysmal in character. Along with this discomfort, paroxysmal attacks of dyspnea and signs of intrathoracic pressure are evident. X ray examination usually locates the mediastinal mass.

Case VI.—J. K., male, aged sixty-eight. Patient's complaints began several months before admission with attacks of sharp sticking pains over the right upper chest appearing at irregular intervals. At first they would last for an hour at a time, but later they would persist for several hours. Several months following the onset of these pains there appeared for the first time a small nodule on the back of the neck. In a short while many more nodules appeared in the neighborhood of the first mass. At about the same time that the new masses were noticed, a persistent cough appeared and great difficulty in swallowing was experienced. X ray showed a neoplasm in the superior mediastinum. An excised gland showed the condition to be a lymphosarcoma.

There are three important diseases of the vertebræ that produce thoracic pain and whose differentiation from one another is of extreme importance. I refer to spondylitis deformans, Pott's disease and malignant disease of the vertebræ. Spondylitis deformans is a vertebral arthritis. Various terminologies have been used to designate this disease: osteitis deformans, osteoarthritis and spondylitis rhizomelic. The entire joint apparatus may be involved with the ossification of the intervertebral discs and ligaments. The bone usually becomes hypertrophied and the cartilages atrophied. As a result, the whole vertebral column may be bound into one mass. The pain produced depends upon the extent and the location of the inflammatory reaction. If the process involves the intervertebral spaces and impinges upon the roots before they unite to form the mixed spinal nerve characteristic root pain will result. On the other hand, if the inflammation attacks the spinal nerve itself at its point of formation, the pain will take on the character of a neuritis. The nerve processes may be involved by the extension of the arthritic inflammation to them, or by direct pressure of the exudate, or by pressure of the newly formed bone. The pain is usually complained of in the area of distribution of the nerve and may be unilateral or bilateral. The discomfort varies from that of a dull ache or drawing sensation to that of agonizing paroxysms. It is increased by all movements involving the thoracic vertebrae and is relieved on lying down. Many cases are distressed after sleeping for some time. Apparently, during sleep, the relaxation of the spastic muscles permits the pinching of the nerves by the vertebræ at their exits. At times, the pain may be so severe as to resemble tabetic crises, kidney stone, cholelithiasis, pachymeningitis externa syphilitica, or cord neoplasm. It is true that many of the cases produce little pain, but those that do, invite serious consideration.

Case VII.—W. J., male, aged seventy-four. The patient's illness began two years before admission with the gradual appearance of pain in the right shoulder. This pain was increased on movement and was accompanied by a squeaky sound. In a short while, he complained of a dull pain in the back and on both sides of the thorax. This pain was particularly severe on bending and resulted in a marked limitation of movement. Gradually, the left shoulder became painful and limited in its excursion. The pain was relieved with rest and heat. Physical examination showed the spine to be rigid and the spinal muscles spastic. There was a level of hyperalgesia at the third dorsal segment and first lumbar segment. The x ray showed a moderate degree of dorsal and lumbar spondylitis. The multiplicity of joint involvement pointed to a polyarthritis.

The tuberculous form of spondylitis or caries gives quite a different picture from that seen in other infectious spondylidites. The disease begins practically always in the body of the vertebræ. Rarely does it start in a joint or in a ligament. The bone becomes soft and caseous or a purulent material is produced. This process is nearly always limited to one vertebræ. As the necrosis goes on, the diseased vertebra collapses and the danger of cord compression arises. More frequently, the spinal canal is narrowed gradually by caseous or purulent material producing a chronic pachymeningitis externa tuberculosa. This process presses upon the nerve roots. The compression may take place in the spinal canal as the nerve makes its exit, or in the intervertebral spaces. The first indication of pain is in the region of the affected vertebræ. The pain is exceedingly intense on movement or pressure. The diseased bone is sensitive to percussion and excruciating pain results on being suddenly jolted. These pains come on usually before signs of compression. The early hyperesthesia of the root area later gives way to hypesthesia as the root degenerates. Many of the cases later refer the pain to the terminal nerve ending. At times a herpes zoster and edema of the area involved may be observed.

A large group of the cases complaining of thoracic pain are produced by neoplasms of the vertebrae. Most of the vertebral neoplasms are malignant. The most common form of tumor is carcinoma, which is always metastatic and frequently multiple. Of the primary malignant tumors, sarcoma and osteosarcoma may be mentioned. In carcinoma, the vertebræ are diffusely infiltrated and subsequently become necrotic and soft. Due to the softening, the vertebræ collapse and a gibbus is produced. The nerve roots, as a result, are not only pressed upon, but they are frequently infiltrated by tumor cells. Clinically, the most important sign is pain. This is often remittent in character, and as a result, diagnoses of muscular rheumatism and intercostal neuritis have often been made. The pain is of two types, one of bone, due to vertebral involvement, and the other root due to meningeal invasion. The bone pains are often worse during the night. This may possibly be due to the fact that as a result of general body warmth there is an increased congestion in the vertebræ with resulting pain. At times, root pain may precede any signs of vertebral pathology by years. This pain is girdlelike in nature and has all of the attributes of a root pain. It is increased by jolting or moving. A primary focus should always be sought for in the mammary glands, esophagus, thyroid, uterus, bronchi, stomach and prostate gland.

CASE VIII.—D. G., male, aged forty-eight. Five months before admission, the patient complained of a gradually increasing pain in the right shoulder, right thorax and dorsal spine. The pain was severe, sharp and shooting in character. A diagnosis of arthritis was made and baking was instituted with indifferent results. Gradually, the pain became more and more aggravated in the back and chest. An x ray of the chest was taken and a diagnosis of carcinoma of the spine was made. In a short while he lost all power in his lower extremities. A few months after the first appearance of pain he developed an irritating, persistent cough with an occasional bloody sputum. X ray examination showed multiple metastases in the right scapula, tenth dorsal vertebra collapsed and a mass in the left lower lung. A cervical gland was removed and microscopic diagnosis of adenocarcinoma was reported. Final diagnosis was primary carcinoma of bronchus with metastases to dorsal spine and scapula.

SUMMARY

1. Chest pains may be classified according to their mode of production as follows:

A. Referred pains: Pains in chest wall due to disease in thorax or abdominal viscera. 1, coronary disease; 2, aortic disease; 3, splenic disease; 4, gastric disease; 5, duodenal ulcer; B, Meningeal pains: Pains which are produced by root irritation. 1, neoplastic, a, extramedullary sarcomata, b, intramedullary gliosis; 2, infectious, a, tabes dorsalis, b, ascending infectious meningomyelitis, 3,, degenerative, a, multiple sclerosis. C. Osseous pains: Pains which are produced by encroachment upon the vertebræ. 1. neoplastic, a, sarcomata (primary), b, carcinomata (secondary); 2, infectious, a, spondylitis deformans, b, tuberculous spinal caries.

2. It is of exceedingly great importance to differentiate clinically between pain which is neuritic in character from one that is root in origin.

Nonspecific Protein Therapy in Sensitization Diseases*

Case Reports of Its Application in Migraine, Epilepsy, Asthma and Hay Fever

RALPH H. SPANGLER, M.D.
Philadelphia

The parenteral injection of a foreign protein for the treatment of a variety of diseases is receiving increasing attention and there are several facts of recent development in the clinical application of the nonspecific reaction to sensitization diseases which are of interest.

1. The recognition today that the repeated injection of small amounts of nonspecific protein substances will bring about certain allergic phenomena which induce a state of antianaphylaxis and nonspecific desensitization.

2. The recognition that a number of diseases which until recently have been regarded as of uncertain etiology and indefinite pathology, are considered at the present time probably to owe their origin to protein hypersensitiveness.

3. The recognition that the altered cellular reactivity following protein injections has been found to be of therapeutic value in a number of symptom complexes of disturbed metabolism, included among which are migraine, idiopathic epilepsy, asthma and hay fever—conditions which recent evidence suggests may be classified among the group of socalled sensitization diseases.

In view of these developments it is interesting to recall that in December, 1911, I read a paper before this branch of the Philadelphia County Medical Society and showed three epileptic patients who demonstrated certain clinical results and laboratory findings which followed biological reactions produced by the intramuscular injection of venom protein (crotalin) solution. That report and several subsequent papers (1) have been recently referred to in the literature as early instances of the employment of a nonspecific protein for definite therapeutic purposes.

At that time, now thirteen years ago, and during the next five or six years, the parenteral injection of nonspecific protein substances for therapeutic purposes was regarded with much skepticism by both clinicians and immunologists. As Miller (2) says in a recent article referring to my preliminary report of 1908, "Spangler's treatment appeared so irrational that no attempt was made in this country to verify his results which in the light of recent developments deserve consideration."

During the past decade, however, many clinical reports have accumulated showing beneficial results obtained with the use of a great variety of nonspecific agents. The rapidly accumulating evidence from all parts of this and other countries has led immunologists and the experimental investigators to search for an explanation of the benefits obtained and today there is probably no problem arousing more interest and being more generally investigated by immunologists than the study of the mechanism of the reaction following the injection of foreign protein substances into the human organism.

THE SPECIFIC AND THE NONSPECIFIC REACTION

A review of the various theories which have been advanced to account for the mechanism of the nonspecific protein reaction, while extremely interesting, cannot be discussed in the space allotted for this paper. It is important, however, in order to appreciate the practical value of nonspecific therapy in sensitization diseases to have a clear understanding of the difference between the mechanism of the specific and the nonspecific reaction.

There are two methods of attacking pathological processes. The one is by means of specific

*Read before the South Branch of the Philadelphia County Medical Society, December 19, 1924.

therapy which aims to influence the cause of the disease—if due to a bacteria, to produce a bactericidal substance; if due to a known specific toxin, to produce an antitoxin; if due to a chemical, to neutralize the chemical agent. The other method is by means of nonspecific agents which, instead of attacking the pathological cause, aim to alter the reactivity of the soil, i. e., to produce a general stimulating effect on cellular activity as a whole—a "plasma activation" as Weischert terms it—by the calling forth of a patient's general resting forces through stimulation of the bone marrow and increased activity of the leucocytes; by enhancing the activity of the endocrine glands with their recognized ability to influence general metabolism; and by shedding antibodies previously fixed in the body "exfoliative stimulation" as Larson explains it.

Petersen terms this mechanism the active stage of the nonspecific reaction. There is, however, also produced by the nonspecific protein reaction an increased tolerance to poisons and toxins due in part to the diminished irritability of the nervous system, as was originally shown by Starkenstein (3). Moreover, Starkenstein, Von Den Velden, Manwaring, Petersen and others have demonstrated that the nonspecific protein reaction alters the permeability of capillary and cell membranes, so that there is possible a freer exchange between the blood plasma and the cells, thus allowing a washing out of the tissue fluids into the blood, as Clark (4) recently wrote. These changes produce certain modifications in the colloids of the plasma which Kolmer and others emphasize as an important factor in the mechanism of the nonspecific reaction.

NONSPECIFIC THERAPY AND ANAPHYLAXIS

The relation of nonspecific therapy to allergic phenomena in general and the part played in immunity by anaphylacticlike reactions produced by parenteral injection of various protein substances has started a widespread investigation and is now admitted by laboratory workers, as well as clinicians, to be of much significance in the fields of biology, pharmacology and therapeutics. While specific protein anaphylaxis is not made use of therapeutically, there is, however, wide use being made of the nonspecific anaphylacticlike reaction for therapeutic purposes, especially for its adjuvant and synergistic action with drugs, organotherapy and some forms of physiotherapy.

AGENTS EMPLOYED

While a large variety of protein substances, such as peptone, proteoses, shattered hemaproteins, milk, crotalin solution, and various serums are being used at the present time to produce nonspecific reactions for therapeutic purposes, the chief difference clinically in the various protein agents employed is largely in the intensity of the phenomena induced. I will not review the relative values of these various agents or the practical advantages in the use of venom protein (crotalin) solution which has been covered in detail in several recent papers (5).

SENSITIZATION DISEASES

With the development of the practical clinical application of nonspecific protein therapy, it is of special interest to note the tendency during the past few years to include among allergic diseases many of the socalled diatheses and systemic disturbances of unknown or indefinite etiology. Such constitutional diseases as rheumatism, gout, arthritis, eczema, some of the protein intoxications and certain disturbances arising from menstruation and pregnancy, all show more or less evidence of allergic or hypersensitization phenomena. In addition to urticaria, hayfever and asthma, regarded as typical examples of the group of sensitization diseases, there has been considerable evidence recently brought forth which points to migraine and idiopathic epilepsy as belonging to the same group of diseases.

In a recent paper on The Treatment of Migraine with Peptone, Miller and Raulston (6) call attention to "certain evidence of the anaphylactic character of the migraine seizure," and in an article by Dr. Joseph L. Miller (2) he points out a number of hypersensitization manifestations in epileptic patients which show evidence of anaphylacticlike phenomena.

While the various diseases of this group present widely different clinical symptoms, it is recognized that they have a number of points in common. They tend to recur more or less periodically; their hereditary characteristics have much in common, pointing to the transmission of a tendency to protein sensitization; the symptoms may be aggravated by nervous influences; after acute infection or pregnancy the symptoms often disappear; an increase of eosinophile cells at some stage of the hypersensitization manifestation is undoubtedly of much significance; and finally, the fact that the symptoms may often be relieved by nonspecific protein desensitization lends additional evidence that such conditions may probably be rightly classified in the group of sensitization diseases.

STAGE OF THERAPEUTIC ACTIVITY

The nonspecific protein reaction is therapeutically active in sensitization diseases during the period of hypersensitivity or when the body cells are being sensitized, i. e., just before anaphylacticlike depression occurs. It is during this period of incubation, the stage which, in a recent article (5), I termed preanaphylactic, i. e., before sensitization is complete, that it is possible to produce, by repeated small size doses of nonspecific protein substances, a condition which corresponds to the antianaphylactic state which occurs in animals after anaphylaxis. This induced antianaphylactic and hyposensitization state, as a rule, is more or less temporary and seems never to last longer than from one to three weeks. This fact accounts for the necessity of repeating nonspecific protein injections at frequent intervals of from seven to twenty-one days in order to keep the patient nonspecifically desensitized.

The question of antianaphylaxis and nonspecific protein desensitization is therefore one of great importance in the application of nonspecific protein therapy to sensitization diseases. Clinical reports also indicate, more and more, that in certain constitutional diseases and diatheses, which show allergic phenomena, protein therapy may likewise produce encouraging results.

EOSINOPHILES IN SENSITIZATION DISEASES AND ANAPHYLAXIS

The more we learn about anaphylaxis in relation to immunity and clinical medicine, the more significance I believe will be attached to the varying percentage of eosinophile cells present in the differential blood counts at various stages of hypersensitization phenomena, and the more will be appreciated the value of the proportional increase of the percentage of eosinophile cells as a guide to the regulation of dose and the frequency of administration of nonspecific protein agents.

An increase of eosinophiles has frequently been noted in sensitization diseases and this fact is being pointed out as one of the most important evidences of the relation of this group of diseases to anaphylactic phenomena. There is a local collection of eosinophiles in the lungs in asthma. In the peripheral blood in both hay fever and asthma, at some stage of the seizure an increase of the percentage of eosinophile elements will be quite uniformly found if repeated differential counts are made. This is also true in certain exudative skin diseases and has been reported in some cases of urticaria and eczema. In cases of migraine and epilepsy, since these diseases have been investigated along the lines of hypersensitivity, a number of reports have appeared to the effect that at one stage or another of the seizure the peripheral blood shows the presence of an eosinophilia.

Since eosinophiles are found increased in various degrees in anaphylaxis and anaphylacticlike states, it would seem plausible to make use of their varying percentage as a guide to the strength of dose and the frequency of administration of nonspecific protein substances which are used to produce anaphylacticlike reactions for therapeutic purposes.

As a matter of fact, since 1912 I have in a number of articles (1) called attention to the fact that repeated small doses of venom protein in the human produce an increase of the percentage of eosinophile cells in the differential blood count. Schlecht's (7) experiments, showing an increase of eosinophile cells in guineapigs and dogs with repeated small injections of various foreign protein substances, confirm my experience.

REGULATING STRENGTH OF DOSE

It would be of the greatest practical value, if a method for regulating the frequency of injection and strength of dose necessary to keep a patient nonspecifically desensitized could be worked out in connection with protein therapy. It might, moreover, be possible, if such a method were established and recognized, to determine when the patient is in a hypersensitization state or is desensitized by noting the percentage of eosinophile cells present in the differential count, without using the biological test of an injection, and having to depend on resulting clinical manifestations.

In my experience with the intramuscular injection of venom protein (crotalin) solution covering a period of fifteen years, during which time more than sixteen thousand intramuscular injections have been given to over seven hundred patients, I have found that a study of the differential blood count before and after injections, with a special reference to the degree of eosinophiles produced, offers a satisfactory guide to both strength of dose and frequency of administration of the protein substance. I have reported this method in detail in previous papers (1, 5), and in submitting it again at this time as a practical guide for the administration of protein therapy in sensitization diseases, I will only summarize my conclusions.

METHOD FOR REGULATING DOSE

As a rule the highest percentage of eosinophiles, following the range of doses (one-four-hundredth to one-fiftieth grain of crotalin solution) which I have used, occurs by the second or third day. In from five to seven days after an injection the eosinophile cells will, as a rule, have dropped to four per cent. or under and the patient may be given another injection. It has been my practice not to repeat an injection if the percentage of eosinophile cells by the fifth day has not dropped to at least four per cent. (Howell's high level of the normal range). Moreover, it has not seemed wise to increase the strength of dose as long as any given strength is producing an eight to ten per cent. eosinophilia on the second or third day after an injection.

Clinical experience indicates that with crotalin solution in doses large enough to produce not more than eight to ten per cent. of eosinophile cells within twenty-four or forty-eight hours after an intramuscular injection, we have an agent which produces a state of cell and glandular stimulation, with a colloidal change of the plasma and altered permeability of the cell walls, which corresponds to that stage in the mechanism of the nonspecific reaction which is of therapeutic value. It is in this state that repeated small sized injections of a nonspecific protein can be used to induce a condition of antianaphylaxis and desensitization.

Case Reports

The practical clinical application of nonspecific protein desensitization therapy by the use of venom protein (crotalin) solution in migraine, epilepsy, asthma and hay fever is illustrated in the following abstracted case histories.

MIGRAINE

Case I.—In April, 1916, a thirty-four year old unmarried forelady came under my care with a history of periodical headaches with which severe vomiting was associated. These had been recurring at four, six, or eight week intervals for ten years or since she was twenty-four years old. A seizure would completely incapacitate the patient for from twenty-four to forty-eight hours. The attacks seemed to be independent of the menstrual period.

This patient's younger brother was subject to convulsions and died at thirty-one years of age after a trephine. Her mother suffered from asthma until her thirtieth year and then migraine developed which disappeared after the menopause. Patient was the second of four children. She was breast fed for four months and then given cow's milk, after which she began to have socalled bilious spells. She had scarlet fever at two years and when a girl says she had much digestive disturbance and constipation. Men-

struation was established at thirteen years, and was always fairly regular. During early adolescence her skin was very sensitive to soaps and she had one attack of skin eruption diagnosed as eczema. She was frequently troubled with hives until she was twenty-four years of age, and then the sick headaches began. Since that time there had been no recurrence of the urticaria.

The patient's eyes were examined and glasses prescribed by Dr. A. O'Malley. Dr. T. J. Byrne treated her nose and sinuses. The urine was negative for sugar and albumin. Blood Wassermann was negative. Alkalinity of blood 176 by the Dare method whose normal average point is 266 (266 milgms. sodium hydrate neutralize 100 c. c. of blood—i. e., the 266 point is normal). Differential leucocyte counts showed an increase of eosinophile cells ranging from six to nineteen per cent. at various times.

Crotalin injections were started and continued at weekly intervals and no migraine seizures occurred from April 16th to September 7, 1916.

During the next six months there were four headache seizures but all without vomiting. The alkalinity of the blood continued to range from 156 to 184. The normal point being 266, her alkalinity was low, and I started to give the patient from thirty to forty grains of calcium lactate by mouth and the crotalin injections were continued each week for two months and then as no headaches had occurred their interval was lengthened to two weeks. With this combined therapy the patient had an interval of seven months without a headache or a vomiting attack. The alkalinity of the blood was increased to 239. At this time the patient decided that the calcium alone would probably be sufficient therapy and I did not see her again for nineteen months. When she did return she reported that the calcium lost its effect six or eight weeks after the injections had been stopped. She had been using, in the meantime, various headache remedies but said she thought she would like to have some more injections as her headaches with the vomiting spells were recurring at from ten day to three week intervals.

Crotalin injections were again started and have been continued, except for one four month interval (during which period she had two migraine seizures) at two to three week intervals for the past three and a half years. The patient also takes from ten to forty grains of calcium lactate daily depending on her prodromal symptoms. This patient has not missed a day's work in the past two years owing to illness, and while she occasionally suffers from headache she has not vomited or had a typical migraine seizure for almost three years. Since she has been kept nonspecifically desensitized the percentage of eosinophiles has ranged between two and seven per cent.

EPILEPSY

Case II.—February, 1921, Dr. L. N. Boston sent to me a forty-one year old hardware salesman who was having convulsions. This man's father suffered from asthma and his mother had migraine. Both parents died from pneumonia. His father's brother had epilepsy.

The patient was the youngest of seven children; he was breast fed and had no spasms when teething. Measles and chickenpox were the only diseases of childhood but from his sixteenth year he had suffered periodically with socalled bilious headaches. He was married at twenty-two and is the father of seven healthy children, the youngest being three years of age.

At thirty four years he had his first convulsive attack on a trolley car; second attack six weeks later. During the seven years before I saw him, i. e., after the convulsive seizures had started, there had been one interval of six months without an attack while taking bromide. For the three years before I started treating him, however, convulsions had been occurring about once a month and several times there were intervals of only two weeks. Twice he had had two attacks in twenty-four hours.

Laboratory examinations included a negative blood Wassermann. The urine contained a moderate amount of albumin but no casts or sugar. The hemoglobin was 78 per cent., the red cells 3,750,000—white cells 6300. Differential count: polymorphonuclears 64 per cent., small lymphocytes 25 per cent., large lymphocytes 5 per cent., eosinophiles 4 per cent., basophiles 0 per cent., transitionals 2 per cent.

Crotalin injections were started and continued at weekly intervals and from February 21st to June 6th the differential count showed on the second or third day after an injection increases of the eosinophile cells ranging from eight to eighteen per cent. From June 6, 1921, to March, 1922, the injections were continued at weekly intervals, but the percentage of eosinophile cells on the second or third day after an injection ranged on the average from four to eight per cent. Only twice did they reach ten per cent. in this nine month period.

If my interpretation of the percentage of eosinophile cells in hypersensitization states is correct, it required from February 21st to June 6th to desensitize this patient nonspecifically. During this three and a half month period the weekly venom protein injections continued to produce a decided increase in the percentage of eosinophile cells; they ranged as high as ten, fourteen, eighteen, eleven, fifteen per cent. From June 6, 1921, to March 3, 1922, a period of nine months, the injections were continued at weekly intervals but the patient remained desensitized according to the eosinophilic index, as only twice did they increase to as high as ten per cent. and their average range was between four and eight per cent. on the second or third day after an injection.

After a year's treatments with weekly crotalin injections, no convulsions having occurred, the interval between injections was lengthened to two weeks. The percentage of eosinophiles continued to remain, with the lengthened interval between injections between three and eight per cent., and no epileptic manifestations having appeared the patient left for a vacation on July 14, 1922. He missed his usual two week injection which was due July 28th and also the one due August 11th. A convulsive seizure occurred August 18th. He had been free from attacks from February 13, 1921, to August 18, 1922, a period of eighteen months. Since this experience he has not missed his crotalin injection every second week and no further convulsions have occurred, now a period of two years and four months. Since crotalin injections were started in this case, now a period two months short of four years, the patient has

had but one convulsion. The occurrence of this seizure at a time when the interval between crotalin injections had been allowed to go over twenty-one days (actually thirty-four days) seems in this case, at least, to point to the probability that the state of nonspecific protein desensitization following an injection does not last longer than two or three weeks.

CASE III.—April 11, 1924, Dr. S. R. Shaner referred a case of asthma which he had had under treatment and observation for several years. The patient, a young lady, was thirty years of age, single, and a librarian. She had suffered from recurrent attacks of autumnal hay fever each season since her fourteenth year, and for the past three years attacks of acute bronchial asthma had also been present.

The family history of this patient revealed that her mother had been subject to nocturnal convulsions at irregular intervals from her eighteenth to her twenty-fifth year. About the time the convulsions stopped typical migraine seizures with vomiting developed, which persisted until the menopause.

The personal history of the patient showed that she was the youngest of four children; was a full term baby and had a normal birth. She was bottle fed and her mother reported that she had much digestive disturbance before teething. As a girl the patient remembered having had many socalled bilious attacks and frequently suffered from hives. At her twelfth year she began to have headaches and vomiting. Menstruation was established at thirteen years; always regular and with little systemic disturbance. Two months later, August, 1908, she presented her first hay fever symptoms and these recurred periodically each year since (sixteen years). Change of climate, rhinological treatments, pollen therapy, and the use of parathyroid and calcium gave only temporary relief.

In the summer of 1921 acute asthmatic paroxysms developed which recurred at several week intervals, mostly at night, for two years. During 1923, the asthmatic seizures became much more severe and were recurring both day and night, so that she rarely passed twenty-four hours without requiring adrenalin or morphine hypodermically to secure temporary relief. The physical signs were typical of an acute bronchial asthmatic paroxysm.

April 11, 1924, the hemoglobin was 78 per cent.; the red cells 3,950,000; the white cells 7200; the differential blood count showed a 9 per cent. of eosinophile cells. On April 12th, 14th, 15th and 16th, during which days one severe asthmatic paroxysm was followed by another, the differential blood counts revealed a 15, 11, 14 and 12 percentage of eosinophile cells respectively.

On April 16th, the patient was given a one six hundredth of a grain of crotalin solution intramuscularly. This was followed by a very mild local reaction and two days later the percentage of the eosinophiles was eleven. The asthmatic attacks continued. April 21st, a second dose of one six hundredth grain of crotalin was given in the other arm, this was followed by a marked local reaction, and two days later the eosinophile cells were 21 per cent. in the differential count. On April 25th there was 16 per cent., and on April 26th 11 per cent. of the eosinophiles present.

April 28th, with 9 per cent. of eosinophiles present, I gave a third one six hundredth grain injection of crotalin solution. This was followed by another marked local reaction. It was interesting to note that there had been an interval of eight days without any asthmatic seizures, when on April 29th, twenty-four hours after the third crotalin injection, the patient had two severe paroxysms. The eosinophiles on April 30th were 16 per cent., and on May 1st 13 per cent., and that night there was an asthmatic attack.

May 5th, with a 10 per cent. eosinophilia present, I gave a fourth injection of one six hundredth grain of crotalin. The local reaction following this injection was good, but not nearly so marked as the two preceding ones had been. Two days after this injection, May 7th, the eosinophiles were 15 per cent. There had been another interval of six days without any asthmatic attacks, when during the night of May 7th a severe paroxysm occurred.

May 9th, the percentage of the eosinophiles was 9 per cent., and May 12th, they were 8 per cent. That morning I gave a fifth injection of one six hundredth grain of crotalin. During the following night a severe and long asthmatic seizure occurred. Two days later the eosinophiles were 13 per cent.

From this date on until the patient went to the country for a vacation, August 4th, she received a weekly injection of crotalin. Following each injection there was a moderate increase in the percentage of the eosinophile cells but they never went higher than 12 per cent. and during the month of July there developed after injections only a 7 or 8 per cent. During the months of September, October and November the percentage of the eosinophile cells on the second day following a crotalin injection did not go higher than 5 or 6 per cent.

Clinically, it is of interest to record that since the hard paroxysm on the night of May 12th, this patient has been entirely free from all asthmatic symptoms (seven months). Moreover, no hay fever symptoms developed during the summer of 1924 (the first season she had missed for sixteen years).

Again, if my interpretation of the eosinophilic index in sensitization diseases is correct, this patient has remained nonspecifically desensitized for the past six months. During this period she has been entirely free from asthmatic manifestations and there has not been present in her differential blood counts at any time following the protein injections what could be termed an eosinophilia.

SUMMARY AND CONCLUSIONS

1. While protein therapy is still in a tentative stage of development, its clinical results are promising and we are now warranted in treating diseased conditions by this means when we desire to aid natural resistance and increase the defensive forces of the system.

2. Recording of clinical observations are of value in studying the relation of anaphylaxis to immunity.

3. Since an increase in the percentage of eosinophile cells is recognized as evidence of an anaphylacticlike state, their relative proportion in hypersensitization states and following nonspecific protein injections may be used as an index to determine the degree of desensitization and antianaphylaxis induced, as well as for the strength of dose and the frequency of administration.

The author's references will appear in his reprints.

Tryparsamide in Syphilis

WILLIAM C. MENNINGER, M.D.
Topeka, Kansas

Tryparsamide is the name applied to an arsenic compound first prepared by Jacobs and Heidelberger (1) in 1917 in the Rockefeller Institute for Medical Research, used first in trypanosome infections and later in the treatment of late syphilis of the nervous system. It is the sodium salt of N-phenylglycineamide-p-arsonic acid, containing 25.32 per cent. of arsenic in the pentavalent form. Tryparsamide is a colorless, odorless powder, readily soluble in water.

EARLY EXPERIMENTAL WORK

The toxic action of tryparsamide was carefully studied by Brown and Pearce (2) in 1919 in various animals. They found that the substance could be given by almost any method of administration to these animals in large doses—a minimal lethal dose varying from 0.75 to 2.75 gm. to the kilogram of body weight for different species. The tolerance of different animal species varied widely, but with one exception, the reaction to toxic doses was of a favorable character. These workers found the toxic effects confined to doses relatively close to the minimal lethal dose, and recovery from sublethal intoxications was remarkably rapid and complete. It was further noted that repeated administration of very large doses at comparatively short intervals of time might be given without incurring dangers incident to cumulative action or to superposition of toxic effects. It was possible to develop a high degree of tolerance —well above that which was fatal for the normal animal.

Brown and Pearce (3) tested the therapeutic action of tryparsamide in a large series of mice, rats, and guineapigs, experimentally infected with various strains of trypanosomes. Very favorable results were produced with doses of from 0.2 to 0.3 gm. to the kilogram of body weight, which is much below the toxic dose. The absence of organic or functional disturbance following therapeutic doses was a significant point. In a second series (4), these workers found a marked curative action in experimentally infected rabbits, with the best advantage by repeated dose therapy.

The action upon spirochete infections (5) was not so striking, although a "very definite effect is produced upon the course of infection by Treponema pallidum. In the case of blood spirochetes, the infection is ameliorated, and even though the spirochetes are not immediately destroyed, the infection is frequently brought to a termination which leaves the animal in a condition not unlike that produced by more powerful spirocheticidal agents. It does possess a considerable degree of spirocheticidal action, but its chief effect is seen in the peculiar manner in which it modifies or controls the course of the infection." The lesions may be favorably influenced out of proportion to the action on the spirochetes.

In three classes of animal infections Pearce and Brown (6) found the trypanocidal action of tryparsamide was much less for Trypanosoma rhodesiense than for Trypanosoma gambiense. The outlook for the drug in the therapy of Rhodesian sleeping sickness was forecasted to be much less hopeful than in gambiense infections, though because of the tolerance exhibited to the drug and the possibility of employing an intensive system of treatment, it was hoped that some benefits might be derived from its use. Smillie (7) has more recently reported on the treatment of *mal de caderas,* a disease of horses in South America, caused by infection of Trypanosoma equinum with tryparsamide, and has obtained encouraging results.

TRYPARSAMINE IN HUMAN TRYPANOSOMIASIS

The use of the drug in human infection by Trypanosoma gambiense was studied by Pearce (8) in seventy-seven cases of both early and late stages, in the Belgian Congo in 1920. The general beneficial effect of the drug was a noticeable feature of its action in both early and advanced cases, as shown by the disappearance of subjective symptoms, by the return of the pulse and temperature to normal limits, by the pronounced improvement of the blood picture, and by well marked gains in weight. Doses of three to seven gm. administered intravenously were sufficient to sterilize the peripheral blood, although relapses were liable to occur unless treatment was continued. Intramuscular administration produced a longer immunity against relapses than did intravenous administrations. The only untoward effect in the seventy-seven cases treated was visual impairment, which was slight in six cases, moderate in seven cases, and marked in four cases. Recovery was complete in ten of these cases, some improvement in three others, and slight in the remaining four. All were advanced cases with marked alteration in the spinal fluid except two. There was no instance of sudden complete blindness, but the condition was one of visual dimness of various grades. In one patient, two doses of four grams at a week's interval was followed by visual disturbance, but in the others more than two doses were given. Pearce believes it is likely that the individual pathological condition of the optic structures in advanced cases is the predisposing factor in the occurrence of this untoward effect.

Since the first work by Pearce, Chesterman (9) has reported a study of the cerebrospinal fluid changes occurring in forty cases of sleeping sickness treated with tryparsamide, and agrees in his results with those of Pearce. Van den Branden and Van-Hoof (10) have reported on fifty-five patients in the Belgian Congo, whose treatment was started by Pearce. Doses of from two to eighty-two grams in one to four courses were given. In the early cases without central nervous system involvement, there were one hundred per cent. cures. In thirty-five advanced cases there were sixteen cures (forty-five per cent.), thirteen other patients were living and well and nearly normal spinal fluids, and three patients died. Morgan (11) is reporting a case treated at the Rockefeller Institute which had been treated

with Bayer 205, and relapsed, with symptoms of marked central nervous system involvement. Following tryparsamide treatment, the patient has returned to excellent health.

EXPERIMENTAL WORK WITH TRYPARSAMIDE

Besides the original work carried on by the workers mentioned above, there have been some published reports of experimental work on tryparsamide.

Two reports have been published regarding the penetration of the drug into the spinal fluid. The first was made by Voegtlin, Smith, Dyer, and Thompson (12) in rabbits. A heavy suspension of Trypanosoma equiperdum was injected into the cranial subarachnoid space of rabbits. No essential difference towards arsenicals has been discovered between Trypanosoma equiperdum, Trypanosoma gambiense, and Treponema pallida. Preliminary investigation demonstrated that trypanosomes thus injected could be recovered in considerable numbers. Tryparsamide and other arsenicals were then injected into the ear vein of the infected animals. After twenty-four hours a careful search was made in at least six different specimens of cerebrospinal fluid taken from various subarachnoid spaces of the brain and medulla. The absence of trypanosomes in these specimens was considered evidence of permeability of the meninges by the arsenical injected or of some trypanocidal derivative. Under these experimental conditions, tryparsamide proved more effective than any other of nine arsenicals used. An amount which was only four per cent. of the minimal lethal dose was eighty-seven per cent. efficient. Sulpharsphenamine with sixteen per cent. of its minimal lethal dose was eighty-two per cent. efficient, being the second most effective arsenical used. Mehrtens, Kolos, and Marshall (13) have found tryparsamide to be positively chemotrophic for nervous tissue as compared to arsphenamine. The spinal fluids of patients who had received previous injections of tryparsamide showed as much as two or three times as great arsenic concentration as those who had received intravenous arsphenamine injections. Spinal irritation increased the arsenic concentration from twenty-five to thirty per cent. over those cases in which only intravenous tryparsamide was used.

The arsenic content of the blood after intravenous injection has been studied by Fordyce, Rosen, and Meyers (14) in 304 blood samples taken after tryparsamide injection, at varying lengths of time. They found a rapid disappearance of the drug from the blood stream during the first fifteen minutes after the injection, the most abrupt fall occurring within five minutes. After twenty minutes and up to four hours, the quantity present in the circulating blood is nearly constant. At the end of fifteen minutes 7.65 per cent. of the arsenic is present in the blood stream, and at the end of seventy-two hours only 0.012 per cent. remains.

In line with the small amount remaining in the blood stream, it was pointed out by Young and Hamilton (15) that at least a part of the drug was excreted in the urine unchanged. A further study by Young and Muehlberger (16) on four cases, showed that in three of them eighty-eight to ninety-five per cent. of the drug was excreted within the first twenty-four hours.

TRYPARSAMIDE IN SYPHILIS

To date relatively few reports of the therapeutic use of tryparsamide in syphilis have been published, since while the drug has recently been approved by the Council on Pharmacy and Chemistry of the American Medical Association, for some time it was not offered for sale, pending the outcome of clinical study. It was stated (17) that the Rockefeller Institute was in entire control of the chemical and biological testing and distribution of the substance. A recent report from Pearce and Brown (18) states that now over sixty clinics and institutions in the United States are using the drug and ten in other parts of the world.

Brown and Pearce (19) summarized the important features of the action of tryparsamide as comparative freedom from untoward effects, a moderate degree of trypanocidal action and slight but definite spirocheticidal action, an unusually high penetrability which enables it to develop a high actual as compared with its potential parasiticidal action, and a remarkable power of reinforcing processes of natural resistance and of promoting recuperation. Therefore the use of the drug should be directed with a view to utilizing these resources and not from the viewpoint of a powerful parasiticidal agent.

The first clinical report made by Lorenz, Loevenhart, Bleckwenn, and Hodges (20) painted a glowing picture for the use of tryparsamide in neurosyphilis, especially generally paralysis. It was also recommended for patients who could not take other arsenicals, for patients who had been proved to be Wassermann fast; for late syphilis occurring in patients past middle age because of its less drastic effect than arsphenamine and neoarsphenamine, and for patients in a poor state of nutrition. They state that the introduction of this drug into the therapy of syphilis was not based primarily upon its spirocheticidal action, which was comparatively feeble, but on certain unusual features of toxicological and therapeutic action observed in experimental animals, such as the promptness of recovery from toxic injury, tolerance to repeated doses, a marked tonic effect, and the ability of the drug to induce resolution and healing of syphilitic lesions, even in the presence of actively motile spirochetes, without increasing the liability to the occurrence of a generalized disease.

Following their first report, Lorenz and Loevenhart along with Reitz and Eck (21) have published their conclusions based on the treatment of 185 cases of neurosyphilis over a two year period with tryparsamide. They state that tryparsamide with mercury salicylate is therapeutically effective in early paresis, meningovascular syphilis, and to a lesser extent in taboparesis, tabes, and in advanced paresis. The beneficial clinic results generally precede the improvement in the serology. Definite paretic psychosis disappears as the result of treatment, with the persistence of mental restoration over a two year period.

The second clinical study to be published was by Moore, Robinson, and Keidel (22). They used the drug in various types of syphilis. From their results in the treatment of eight early syphilitic cases, they concluded the drug to be contraindicated because of its comparatively feeble spirocheticidal activity. In twenty-four cases of late syphilis (tertiary and

latent) they found it inferior to arsphenamines, and if used should supplement mercury and arsphenamine and not supplant it. Other than central nervous system syphilis, it had no effect, and consequently these writers feel it should be restricted to neurosyphilis and possibly vascular syphilis. In forty cases of neurosyphilis, twenty-eight cases were arrested, five improved, and seven unimproved from a clinical standpoint, and with the majority showing improvement in the spinal fluid findings. In a later report (23) these workers give their conclusions based upon the treatment of 133 cases of neurosyphilis. They state that in primary and secondary syphilis, or in tertiary syphilis without nervous system involvement, the therapeutic involvement is so slight as to preclude its further general use in these types of infection. In neurosyphilis, on the contrary, tryparsamide therapy produces favorable clinical and serological results, which I believe cannot be equalled by other forms of treatment.

The changes in the spinal fluid following tryparsamide treatment have been noted by most writers, and especially by the report of Solomon and Viets (24), who treated about one hundred cases of neurosyphilis with the drug. In nearly every case the cell count was reduced to normal after six or eight injections; the globulin was reduced to a relatively small extent; the Wassermann reaction in the spinal fluid was not greatly affected in the majority of cases, and the colloidal gold curve was apparently less affected than any of the other spinal tests. Clinical improvement occurred in some cases, but was no more satisfactory than with older methods of treatment. They believe that the best results may be obtained by the use of tryparsamide with other antisyphilitic methods. In contrast to the serological changes without much clinical change, is the report of Wile and Wieder (25) who found in the treatment of fifty neurosyphilitic cases (twenty-one general paretics) the clinical improvement was striking, although not paralleled by striking corresponding changes for the better in the spinal fluid. Kennedy and Davis (26) also note the more striking clinical results but call attention to the fact that while the serological results are at first glance disappointing, tryparsamide therapy appears to influence most of the tests that have the greater clinical significance (cell count and colloidal gold test). They feel that in all clinical types of neurosyphilis and particularly general paralysis the therapeutic results obtained with tryparsamide compare favorably with the best results obtained for other forms of treatment. Ebaugh and Dickson (27) also state that tryparsamide gives frequently good clinical results although the serological changes are meagre and transitory. Their results, based on the treatment of fifty-two cases of general paralysis, is much more encouraging than any previous method of treatment.

Other clinical studies on tryparsamide therapy have been made, both in this country (Viner (28), Hindman (29), Blair (30)) and abroad (Sicard (31), Cheinisse (32), Guillain and Girot (33), Claude and Targowla (34)). Both the latter references cited do not regard tryparsamide therapy as of any advantage over other forms. Guillain and Girot base their conclusions on the treatment of five cases, three of which were general paralysis. Claude and Targowla term tryparsamide therapy as inoffensive, and in a limited test found no clinical or serologic improvement in definite cases of general paralysis.

ACTION OF TRYPARSAMIDE ON THE OPTIC TRACT

Pearce first noted the visual effects as the result of tryparsamide therapy on the cases treated in the Belgian Congo. It has been mentioned in most of the clinical studies made, and some experimental work has been done on the subject. Special clinical studies have been made by Woods and Moore (35) and by Lillie (36). The various reports place the optic nerve involvement between three to forty per cent., the majority of which are temporary, three to five per cent. being permanent. In the cases showing visual disturbances, if a rest is given in the treatment, eye symptoms do not recur with further tryparsamide therapy. Woods and Moore feel that preexisting syphilitic disease of the optic nerve or retina is not necessarily a contraindication to the use of the drug, and Lillie states that it is not contraindicated by pathological changes in the fundus. The latter writer found in his select series of cases that tryparsamide was not more harmful to the eyes than any form of arsenic used in the treatment of syphilis of the central nervous system.

SUMMARY

1. Tryparsamide is an arsenical compound, containing 25.32 per cent. arsenic in the pentavalent form.

2. Experimental and clinical studies have shown it to be an effective therapeutic agent in cases of trypanosomiasis.

3. Its use in the treatment of syphilis is based more upon its power to penetrate nervous tissue, rather than its spirocheticidal power.

4. From clinical studies, it is found advantageous in the treatment of neurosyphilis, particularly general paralysis, but is ineffective in primary and secondary syphilis, and in tertiary syphilis in which there is no involvement of the central nervous system.

5. The method of treatment usually advised is in either two or three gram doses, dissolved in ten c. c. of sterile water, given intravenously, once a week, for a course of eight to twelve doses. A rest period of one to three months is given between courses. One or more courses may be given.

6. The only serious disadvantage is encountered in visual disturbances, which occur relatively infrequently, and need not cause permanent damage if careful attention is given to the dose of the drug.

Cases in Which the Test for Pancreatic Efficiency Has Been of Clinical Assistance

Clinical Report No. 1

ANTHONY BASSLER, M.D.
and J. RAYMOND LUTZ, M.D.
New York

(*Concluded from page 278*)

Case VI.—Mrs. A. M. C. The patient was referred by Dr. Adams, of Whitestone, Long Island, September 12, 1924; widow, aged sixty-two, no children. Family and personal histories were negative. The present illness began about February, 1923, when foods commenced to cause distress; this gradually grew worse, when a pain developed in the upper right abdomen. The patient at first thought she might have strained her side, because the pain came on quickly; she said she thought she had a fever for a few days. The soreness of the right side continuing and the gastric distress becoming worse, Dr. Adams considered the possibility of gallstones. An x ray examination was made in June, which was negative as to proving the presence of gallstones. The patient had had a nocturia two to three for years, but many examinations of the urine did not prove anything.

Physical examination showed a well nourished and proportioned woman, blood pressure 140/90. The examination was negative with the exception of a marked stiffening of both lobes of the liver and a distinct tenderness on pressure in the median fissure. The laboratory examinations showed negative urine, normal renal efficiency test, and the following bile and pancreatic tests: September 15th, A fraction 20 c. c., light yellow, cloudy, mucus xx, pus xx, and Bassler test twelve units; B fraction, 70 c. c., dark brown, cloudy, mucus xx, pus xx; C fraction 60 c. c., light yellow, cloudy, mucus xx, pus xx. The diagnosis was chronic cholecystitis, perhaps with stones, and secondary fibrosis of the liver. Operation was refused.

Progress: The Bassler test on October 2d showed ten units; on October 9th, eight units; October 16th, eight units; October 27th, six units; October 31st, four units. All this time the patient complained of feeling no better, while the cytology of the bile fractions remained as first reported. Operation was again urged, although it was felt that so much serious damage had occurred in the liver that the improvement here would not make it worth while. However, the pancreas was diminishing in function, and to save this organ the need for surgery was emphasized. The suggestion was not accepted, however, and treatment was continued, the diet being further modified, the pills kept up, and aspirations made twice weekly through November and December. In about mid November the patient said she felt much better, although there was only slight improvement in the bile fractions but a gradual rise up to eight units in the pancreatic efficiency, at which point it then remained.

Comment: This case proves that cholecystitis may not improve under bile aspirations and that when secondary liver pathology is present it is wiser to

insist upon operation since it is the more important when there is a decline of pancreatic efficiency. We feel that with the improvement claimed by the patient the lowering of the unit reading is significant. It is probable that under continued treatment she may be held steady but our experience has been that when one can prove a permanently low or especially a lowering of the unit findings operation should be urged with firmness to save the pancreas from chronic pancreatitis.

The next case reported is a complicated type of case of chronic colecystitis, pancreatic deficiency, chronic interstitial appendicitis, and colonic stasis in which the pancreatic efficiency test was of value in a negative way for diagnosis.

Case VII.—Mrs. A. M. The patient was referred by Dr. P. Goldfader, Brooklyn, on January 5, 1924, widow, no children, housewife, aged forty-four. The patient's father and mother were living and well. The personal history was negative in significant ways. The present illness began about five years before, with gradually increasing belching of gas. At times there were attacks of pain in the epigastrium and occasionally some vomiting. About one year ago there had been an attack of abdominal pain which required morphine, and another attack occurred four weeks ago. The gastric distress from gas distention at the early stage was sometimes so severe that the patient could not stretch out in bed on her back, but would be obliged to get up and walk about or take some medication to relieve the distention and distress. She was seen by several physicians, and a summary of things done and diagnoses made was as follows: negative urine, negative Wassermann, negative blood culture, negative blood count, poor filling of the pylorus, poor filling of both outlines of cap, poor gastric peristaltic power, defect on lesser curvature of cap (made on the second x ray examination but not confirmed by the first), six hour barium meal in the large intestine with suggestion of loop of small intestine involved in splenic flexure of colon, appendix well filled and stagnant at seventy-two hours. The second set of films was interpreted by us as negative in all ways except for a globular and stagnant appendix.

Physical examination showed blood pressure 110/87, marked tenderness on pressure over the gallbladder, slight over the appendix. The skin was dry and the patient said there was much itching. The left lobe of the liver was stiffened. Laboratory examinations disclosed negative stool, urine, and test meal, a bile aspiration that was essentially normal in all fractions, and a Bassler test reading of fifteen units. The treatment was conservative for a while, but the removal of the appendix and gallbladder was recommended if warranted. On a bromide and valerian mixture to control the belching, a hypocholesterin diet, Carlsbad salts, and much walking, the patient made a steady improvement and on July 8th said she felt perfectly well, the appendix still being retained.

Comment: It is probable here that a return of symptoms will occur, although if the patient is continued more or less on a diet, with Carlsbad salts and daily walks, they will be held in abeyance. The excessive belching was certainly due to the nervous condition as much as to the pathological condition of the gallbladder, which because of the negative Bassler test could not be affected very much, a suggestion that came from the bile aspiration as well, although from a diagnostic viewpoint we do not attach much importance to this. In many of our cases we have negative findings with positive pathology, and in others positive biles with negative pathology. We feel it answers in a diagnostic way in a percentage sense in a large group of gallbladder patients but in the individual case judging from operations, slides of tissue and a study of infections, it can only be considered as of minor value. What is interesting in this connection is that in our experience the most commonly found type of gallbladder with stones often gives a nonconclusive and even negative result in the Lyon-Meltzer test in so far as pus, mucus, mucopurulent clumps, bacteria and even crystals are concerned. After most conscientious effort we candidly admit our failure frequently to be able to judge the different cells as to where they come from and their significance in accurate enough ways for clinical deductions.

In our experience also, when an infection exists without stones the Lyon-Meltzer test is more likely to be of help in a clinical way. We still hold to our contention that the method drains the biliary apparatus—the ducts and biliary radicals completely and the gallbladder only in small part and only according to the energy of drainage of the ducts in which the flow of the main current through them causes a vacuum or an attraction flow by effect on the opening of the cystic duct by the bile running past. We still do not believe that in the vast majority of instances in which dark B fractions are obtained that this is other than resident and condensed bile from the main ducts and largest biliary channels in the liver and not from the gallbladder *per se,* and we still have to be convinced that "crossed innervation" or vermicular action of the gallbladder enters into any significant part of obtaining it even when magnesium sulphate solution is employed as the stimulant.
